A wound is the physical manifestation of an injurious force exerted on the body. Accordingly, careful evaluation of the patient as a whole is critical. A common pitfall is focusing on the most visible injury and not recognizing other lesions that were caused by one event, such as trauma. Understanding the injurious mechanism also enables better prediction of the wound’s severity. As an example, blunt force injuries have significantly greater potential for diffuse tissue nonviability and are consequently more prone to infection. Once all injuries have been catalogued, each may be addressed. Important considerations include knowing how the patient was injured (shear, abrasion, compression), whether the location of the wound is in a cosmetically or functionally vital area, and whether potentially confounding influences on the potential for healing are present.

**INJURY TO UNDERLYING STRUCTURES**

When sufficiently breached, skin fails in its protective role and may allow underlying structures to be injured (Fig. 186.2). Diligent assessment of the functionality of surrounding anatomic structures is of utmost importance.

**Presenting Signs and Symptoms**

Wound repair may be sought intentionally or be required following evaluation of other complaints, such as a syncopal event. It is not uncommon for patients to be entirely unaware of their wounds (as in trauma) or to be unimpressed with the severity of their lesion because of more painful conditions, such as a fracture. For all these reasons, a thorough physical examination plus evaluation of all wounds is required. Through this evaluation and assessment of the patient’s unique situation, an appropriate approach may be undertaken to address a wound. The overall risk for infection and the likelihood of complications can be predicted by considering wound and host factors. A major pitfall of wound management is fixation on the wound without sufficient attention to the host.

redundant tissue. If it extends beyond the original margins of the wound, it is called a keloid. Depressed scars create shadowing (consider the visibility of age-associated wrinkles), which makes them appear darker than the neighboring reflective surfaces. The color of a scar results from its vascularity and pigmentation with respect to surrounding healthy tissue. Melanocytes do not produce pigment at the same rate in injured and healing tissue or in scars as they do in normal tissue.

All these factors in scar formation vary among individuals. Some patients heal very well, whereas hypertrophic keloids invariably develop in others. However, steps to improve outcomes generally remain the same in emergency management.

**Fig. 186.1 Skin anatomy.** The layers of skin—epidermis, dermis, and connective tissue—all play important roles in wound healing. The dermis is the most important and thickest, but it thins with age or steroid use. Note the tearing appearance of the skin of this elderly patient, who fell on an escalator.
Tendon function should be assessed throughout its range of motion. It may help to ask the patient to estimate the position of a body part at the time of the injury, especially with hand injuries. Tendons may be partially lacerated but their range of motion may remain intact, thereby misleading the practitioner. Patients’ complaints of pain or subjectively decreased range of motion, despite objectively normal findings on examination, should raise suspicion for partial disruption.

Nerves can be injured by the wounding mechanism itself or by iatrogenic maneuvers, especially indiscriminate ones. Clamping, blind probing, and injudicious débridement may all disrupt adjacent nerves. The hands and face are at greatest risk because nerves run in close proximity to the vasculature; zealous attempts to control bleeding vessels can result in damage to adjacent nerves. Injected anesthetics may also injure nerves as a result of pressure necrosis in finite spaces. Examples include injections into the olecranon grooves or foramina in the hard palate of the mouth.

Muscles are highly vascular tissue and are often disrupted with deep wounds. Because muscles are dynamic units, subsequent hematomas, scars, or infection can result in dysfunction. Unnecessary débridement should be avoided and bleeding controlled with direct pressure. Muscle can usually be repaired by securing the surrounding structures, thereby placing the cut surfaces of the muscle in direct apposition. Muscle tissue should be repaired directly only when the foregoing maneuver is insufficient.

Occasionally, a wound is the first sign of an underlying fracture, either because the skin was injured with the force carried onto the bone or because the broken bone edges penetrated the skin from inside.

**FOREIGN BODIES**

Foreign bodies can be driven into wounds through innumerable routes of entry. Common situations include shattered glass in motor vehicle accidents, vegetative material in wounds during outdoor pursuits, and puncture wounds through footwear. Foreign bodies increase the risk for infection and may prevent healing. The following section on puncture wounds specifically addresses foreign bodies in these situations. For additional discussion of foreign body evaluation and management, see Chapter 187.

**TREATMENT**

The emergency physician (EP) can close most wounds; some situations requiring specialist consultation are listed in Box 186.2.

**WOUND PREPARATION**

To meet the goals of reducing risk for infection, minimizing damage to underlying structures, and forming a functional and cosmetically acceptable scar, preparation of the wound can be tantamount to or may surpass closure in importance. An appropriately prepared wound has been anesthetized, has been decontaminated of large particles or foreign bodies, has minimized bacterial counts, and has edges amenable to optimal repair.

**TIPS AND TRICKS**

**Wound Preparation**

Always place the patient in a comfortable position, preferably supine.

Remove as much gross contamination as possible before pressure irrigation.

Lidocaine with epinephrine may be used in most areas of the body.

Water is an acceptable initial irrigating fluid for many wounds. Hair does not need to be removed.

**Sterile Technique**

Use of sterile fields, gloves, caps, masks, and gowns is de rigueur in operating room surgery but not as well established in routine wound closure. Studies have shown that the use of sterile versus nonsterile boxed gloves in routine wound
management may not have a significant effect on the rate of infection. powdered gloves should be avoided because of their association with granuloma formation, and EPs must be aware of possible latex allergy.

Anesthesia
In general, anesthesia should precede significant efforts at cleansing, irrigation, exploration, and closure. Despite long-held dogma, lidocaine with epinephrine can be used in most areas of the body, including the majority of hand wounds and digital blocks. For a complete discussion of local and regional anesthesia, please see chapter 188.

Wound Cleansing and Irrigation
The goals of wound cleansing and irrigation are to remove gross contaminants and particulate matter, reduce bacterial counts in the wound, and avoid impeding the host’s responses and natural defenses. In general, ideal wound irrigation requires sufficient pressure and volume while providing drainage and preventing operator exposure. If large particles are present, gross decontamination should be performed before pressure irrigation. A sink, an intravenous infusion set, or holes made in the plastic top of a saline solution bottle can be used to make a spray of water for removing leaves, dirt, and other large contaminants. Following gross decontamination, the pressure of the irrigating stream must be sufficient to overcome the adhesive force of bacteria (5 to 12 psi). Such pressure can be produced with a 35- or 50-mL syringe and a 19-gauge catheter or a commercial device with an integrated splash cup. Excessive pressure during irrigation may actually cause additional harm and should be avoided.

The volume of irrigant sufficient to decontaminate wounds is unresolved. However, because bacteria may be present in all sections of a wound, all surfaces of a wound should be exposed to the irrigating stream.

The composition of irrigating fluid has been debated and studied inconclusively, but no significant inferiority has been demonstrated for normal saline. Antiseptics such as povidone-iodine kill bacteria in wounds, but they can also kill fibroblasts and harm normal tissue in the process, particularly if the antiseptics are not diluted to less than the typical 10% preparations. Anecdotally, some clinicians reserve diluted povidone-iodine irrigation for grossly contaminated or high-risk wounds and use saline solution for other wounds, but no conclusive evidence supports this approach. At the other end of the spectrum, some studies demonstrate favorable results when irrigation with tap water is used rather than sterile water or saline solution. The benefits of using water for irrigation include ease of use and drainage and some modest cost savings. Tap water may be used for irrigation of wounds on body parts well suited to it (e.g., the hand), either alone or as an adjunct to subsequent pressure irrigation, depending on the risks associated with the individual wound and host. In summary, the composition of the fluid is much less important than its mechanical action in decontaminating a wound.

Wound Edge Preparation
Hair does not generally need to be removed. Shaving has been shown to increase the rate of infection. Hair that directly and substantially interferes with proper suture placement can be clipped near the wound edges with scissors.

In general, one should not débride any more than is absolutely necessary to remove clearly devitalized tissue. An irregular, undulating wound may be superior to a straight, linearly excised wound because the longer surface area results in better tensile strength across the healing wound and it maintains the natural contours and marks of the original skin. If débridement is necessary, high-quality forceps and a No. 15 scalpel blade should be used.

Planning the Repair
The first decision to be made is whether to close a wound primarily. The time elapsed since the injury, the degree of contamination, host factors, and wound factors all play a role in deciding the best option. Primary closure refers to mechanical apposition of the wound edges with subsequent wound healing. Delayed primary closure is the same technique carried out 4 to 5 days after the injury. At this point the host’s defenses against infection have been mustered locally, and the risk for subsequent infection with primary closure declines significantly. In secondary closure (secondary intention), gaps between the wound edges become filled with granulation tissue by the body and reepithelialization subsequently occurs.

No well-accepted studies have established firm guidelines for the timing of closure on different portions of the body. Nonetheless, many clinicians agree that certain wounds on the face and head, especially in pediatric patients, have such a low risk for infection that they may be closed after protracted times from injury, including up to 1 to 2 days later. However, wounds of the same size on the hand or forearm of adults probably do have a higher risk for infection after passage of a similar amount of time from injury.

If the decision is made to close a wound primarily, various options are available. As with almost all decisions in wound management, more than one alternative may be correct, but one option is often best. Methods available for closure include sutures, staples, tissue adhesives, and wound tape or strips.

Wound Closure Techniques

SUTURE REPAIR
Sutures offer the most detailed and meticulous closure option, arguably the greatest tensile strength across the wound, and the best choice for certain considerations such as the amount of time that they must remain in the body. However, sutures can be time-consuming to place, require the discomfort of anesthesia, and typically require removal later. Additionally, a suture is a foreign body with attendant risk for infection and inflammation. In particular, EPs should avoid placing deep sutures in a high-risk wound. Monofilament, braided, absorbable, and nonabsorbable sutures also have varying risk for infection, as well as raise other concerns.

Selection of sutures for a wound should be based on size, absorbability, tissue reactivity, risk for infection, and ease of use. In general, nonabsorbable and monofilament sutures are the easiest to use and have the least tissue reactivity and risk for infection. They are best for percutaneous closure. Traditionally, absorbable suture is used for subcutaneous closure. However, some cutaneous closures can be done with absorbable suture, thus obviating the need for removal.

At a minimum, four basic suture patterns should be at the command of EPs: the simple interrupted suture, the corner...
stitch, and two mattress suture techniques. One should master the simple interrupted pattern first and then move to the others and subsequently to more advanced subcuticular and plastic techniques as required (Fig. 186.3, A and B).

**Simple Interrupted Suture** Though simple in name, proper placement of an interrupted suture requires fastidious practice. Effecting proper wound apposition with regard to the height of each plane of skin and eversion of the closed product will result in more exact healing and a flatter scar. The angle of entry is often suggested to be 90 degrees; however, because the goal is to achieve a trapezoidal cross-sectional stitch with a wider base than top, the angle of entry can exceed 90 degrees. Simply stated, the needle should enter the skin pointing away from the wound edge and should exit the skin on the opposite side of the wound pointing toward the wound edge. Proper placement of an interrupted suture requires fastidious practice. Effecting proper wound apposition with regard to the height of each plane of skin and eversion of the closed product will result in more exact healing and a flatter scar. The angle of entry is often suggested to be 90 degrees; however, because the goal is to achieve a trapezoidal cross-sectional stitch with a wider base than top, the angle of entry can exceed 90 degrees. Simply stated, the needle should enter the skin pointing away from the wound edge and should exit the skin on the opposite side of the wound pointing toward the wound edge.

**Running Suture** The tenets of eversion and alignment of skin planes are the same if the suture is continued in running fashion. After starting at one end with a simple interrupted pattern, the needle end of the suture is run along the length of the wound. Tying the needle end of the suture to the last-placed loop finishes the suture.

**Running Subcuticular Sutures** Subcuticular sutures are more difficult to master. They are useful in that the entire suture remains under the surface of the skin and typically does not need to be removed because absorbable sutures are used. However, many wounds that were previously closed with subcuticular running suture and were of low tension and of some cosmetic importance are now amenable to closure with tissue adhesive.

**Deep Sutures** Subcutaneous or deep sutures are useful to eradicate a large dead space that could accumulate hematoma and to give structural support to the wound and skin. By drawing the skin edges closer together, these sutures also reduce the tension needed to close the wound percutaneously or may allow closure of the skin with tissue adhesive (Fig. 186.4, A and B).

**Corner Stitch** A corner suture should be considered when a Y- or V-shaped incision is encountered. The shape of the wound should be assessed for the most advantageous flap to secure into an apex. A corner suture encompasses both percutaneous and subcutaneous portions, but as a single first stitch it can achieve excellent overall wound alignment and thus facilitate placement of subsequent interrupted sutures to finish closing the wound (Fig. 186.5, A and B).

**Mattress Sutures** Both horizontal and vertical mattress sutures provide, as a single benefit, better eversion of the wound edges than other sutures do. The horizontal mattress pattern has the additional benefit of some added speed by covering more linear wound length with each knot tie. However, it does result in more pressure on the epidermis by the suture material, which can have cosmetic effects. Horizontal mattress sutures may be useful to evert a problematic section of wound that has a tendency to roll inward. It may then either be replaced with interrupted sutures to hold it in place or be left as is with timely suture removal. Similarly, an isolated vertical mattress suture may be useful to effect better skin eversion (Fig. 186.6).

**Staples** Staples can be used in many places where sutures would also be appropriate. Staples also have the benefits of speed and ease of placement and removal. However, staples may offer somewhat less meticulous closure and have a tendency to leave punctate marks alongside the linear scar. For this reason they should not be used for facial lacerations, on fine skin, or

---

**Fig. 186.3** A and B, Simple interrupted suture. This is easy to do, harder to master. Enter the skin pointing away from the wound edge and exit the skin pointing toward it to achieve a trapezoidal cross section and slightly everted skin edges.

<table>
<thead>
<tr>
<th><strong>TIPS AND TRICKS</strong></th>
</tr>
</thead>
</table>

**Suture Placement**

Use longitudinal traction to assess how the wound edges correspond and affix the wound (even temporarily) to maintain appropriate alignment. If you place a suture that seems poor, use the spot to place another knot and remove the original one. Muscle can typically be repaired by aligning adjacent tissue. Do not place sutures in high-risk wounds. The goal of suturing is to have a trapezoidal stitch to disperse tensile force. Sutures should be removed at the earliest appropriate time.

Fig. 186.4 A and B, Deep suture. Use deep sutures with a buried knot to bring wounds closer together and to decrease tension on the edges of the skin.

**RED FLAGS**

**Wound Repair**
Insufficient preparation will also create issues with wound treatment and resolution. Tendons may be partially torn or lacerated while range of motion remains intact. Thorough evaluation of any suspected lesion is thus warranted. Excessively tight sutures—or those without appropriate angles—place an undue amount of pressure on the epidermis that increases the risk for tissue dehiscence and decreases the probability of a good cosmetic outcome. Negligence in providing appropriate aftercare and home care instructions increases the likelihood that the patient will return to the emergency department and decreases the prospects for good recovery from the injury.

Fig. 186.5 A and B, Corner suture. Use this stitch to secure a triangular flap into an apex for rapid reapproximation of the wound architecture.

Fig. 186.6 Mattress sutures. When wound sections are difficult to properly.evert, consider a mattress suture. A single horizontal mattress suture (arrow) corrected a depressed area of the laceration.

in other areas where cosmesis is of particular importance. Although staples are frequently used to close scalp wounds, it is wise to ask patients about their preferred sleeping position and whether they wear headgear in sports or work because staples can be uncomfortable if direct pressure is applied against them during wound healing. Staples are most often used to close wounds on the proximal ends of extremities.

**Tissue Adhesives**
Tissue adhesives have been approved for use in the United States since 1998. The majority of products today consist of 2-octylcyanoacrylates. These compounds are similar to cyanoacrylate, commonly known as superglue. Additional modifications to the chemical composition have been made in
an effort to reduce tissue reactivity, increase pliability of the finished bond, and make the substance more suitable for use on human skin. Studies have demonstrated antibacterial properties of these products as well.\textsuperscript{13}

These substances were originally thought to replace suture closure in 25\% to 32\% of wounds, but it is unclear how often they are actually used in lieu of traditional repair. The most common use of tissue adhesives is for low-tension, nongaping wounds on the face, particularly in pediatric patients. Wounds that would otherwise be closed with 5-0 or 6-0 suture may be considered for adhesive repair. Adhesives are also useful for small avulsion injuries with flaps and occlusion over abrasion injuries as a protective barrier. The material is not suitable for use within the wound itself. Tissue adhesives should not be used in areas of high tension (e.g., across joint surfaces) or to close significantly gaping wounds. Aftercare is similar to that for other repair mechanisms, but the tissue adhesive will gradually slough off without assistance.

**Wound Tape and Strips**

Wound tapes or strips may be an option for wounds in which placement of a foreign body (i.e., suture) may be disadvantageous, in initial management of wounds that may undergo delayed primary closure, or in wounds with a protracted time until treatment. Many wounds that were previously closed with wound tapes or strips are now amenable to closure with tissue adhesive. Examples of wounds and their preferred and alternative closure methods are presented in Table 186.1.

**TIPS AND TRICKS**

**Placement of Adhesive**

Place the patient so that any excess adhesive runs away from important structures such as the eyes.

Have both hands free to place the adhesive; an aide may be useful.

Because each brand of adhesive is different, ensure that the number of coats recommended for the product is applied. Maintain the wound in the desired position for a sufficient amount of time.
In the presence of infection or when the clinician decides to use prophylactic antibiotics, a fluoroquinolone may be the best choice because of improved *Pseudomonas* coverage.17

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Too often, aftercare equals afterthought with underemphasis, lack of instruction and documentation, and inadequate knowledge of evidence-based principles. As in other aspects of laceration and wound care, the aims of aftercare are to optimize the chance of a wound healing without infection and with a functional, aesthetically pleasing scar. Generally accepted principles that promote wound healing include maintenance of a clean environment, immobilization, and elevation to reduce edema.

Application of an antibiotic ointment is commonly recommended. Whether the petroleum vehicle promotes a moist environment for reepithelialization or the antibiotics have an actual effect is unclear, but at least one study supports the use of these ointments.18 Immobilization should be considered at least until epithelialization occurs (usually 2 days) or considerably longer in wounds subjected to high tension (e.g., laceration over the kneecap or shin). Optimal times for removal of sutures (for a wound that is not under tension) from various body parts are listed in *Table 186.2*.

The patient’s scar represents a permanent reminder of the wound, but the medical record is also an enduring account of the events. As a simple guideline with regard to wound documentation, “if you did it or said it, write it” (see the “Documentation” box). Critical elements of record keeping include a description of the mechanism, the patient’s history, and previous home care of the wound; documentation of the function of surrounding structures before and after any medical maneuvers; and description of the steps taken to reduce infection, search for foreign bodies, and close the wound. Furthermore, the instructions given to patients need to include precautions for return, signs of infection, and step-by-step short- and longer-term instructions for aftercare of the wound. Pitfalls in documentation are inadequately addressing the search for a foreign body, irrigation, and assessment of surrounding function, as well as failure to describe the wound’s length and complexity.19

</table>
Aftercare outlined previously, patients who have a tendency to form hypertrophic or keloid scars should be identified by the EP and informed of treatment options available to decrease the size of the scar. Although many methods have been studied, the only treatments with sufficient prospective data to support their use are silicone gel sheets and intraleisional corticosteroid injections. Additionally, pressure or paper taping and massage over developing scars are simple measures that may be initiated soon after initial wound healing. Sunscreen use is important during the first 6 months to 1 year. Certain topical preparations have been promoted to improve scars aesthetically. Vitamin E cream is popular and available over the counter, but no well-conducted study exists to show its effectiveness for acute lacerations, and at least one study has shown a detrimental effect. An onion extract (Mederma) is promoted as a way to make scars “appear” softer and smoother. One prospective study is cited in the company’s literature, but no large studies have yet been published to support its use.

Aftercare of wounds is largely directed and conducted by patients themselves. Consequently, patients need a thorough list of return precautions, including signs of infection: increased redness, pus from the wound, more swelling than they think is appropriate, and excessive pain. Any of these situations should be reason to return to the ED.

In addition, a persistent foreign body sensation may represent just that, and the patient should return for further evaluation. Some EDs perform a routine wound check at 48 hours, although for uncomplicated wounds in an informed patient, this approach is not necessary. The timing of suture removal and sun avoidance or the use of sunscreen should be discussed in relation to aftercare. A preprinted sheet detailing “if-then” scenarios and expected occurrences is useful. Because many wounds are treated at home, information on what types of wounds require evaluation in the ED in the future may result in better prehospital home care and more effective use of ED resources.

KEY POINTS

- Retained foreign bodies (FBs) can cause pain, infection, delayed healing, nerve and tendon injury, masses, and functional impairment.
- Specific injuries, such as those caused by broken glass or surfaces with gravel and stepping on objects, are particularly prone to retained FBs.
- Wounds should be explored for FBs with adequate anesthesia and lighting in a bloodless field.
- Plain radiographs are useful in evaluating for radiopaque FBs and should be ordered commonly.
- Plain films may miss nonradiopaque FBs such as wood, plastic, and vegetative matter. They may also miss radiopaque FBs that are tiny, obscured by bone, or in areas that are difficult to obtain quality images, such as the face or sole of the foot.
- Ultrasound scans and portable fluoroscopic studies may aid in localization and removal of FBs. Computed tomography and magnetic resonance imaging are rarely indicated.
- Neither exploration nor imaging alone can rule out an FB. The two should be used in combination in most instances. No wound is too small or superficial to harbor an FB.
- Careful discharge instructions are crucial and can minimize the morbidity and medicolegal risk associated with retained FBs. Patients should be informed that it is impossible to detect all FBs, be told what to expect in the event of a missed FB, and be given appropriate referral should these circumstances arise.
- Direct exploration of wounds plus visualization of tendons placed through a full range of motion is necessary for proper evaluation of tendon injuries.
- A detailed neurovascular examination is required to identify possible nerve lacerations.
- Most tendon and nerve lacerations can be repaired on an outpatient basis. Ensuring appropriate and timely follow-up is important.

RETAINED FOREIGN BODIES

EPIDEMIOLOGY

Open wounds are frequent reasons for emergency department (ED) visits. The true incidence of foreign bodies (FBs) in wounds is unknown, but with more than 5 million estimated lacerations repaired in EDs in 2007, wound FBs surely occur in such a significant number that all emergency physicians (EPs) will encounter them. Wound FBs are frequently missed on initial evaluation. Seventy-five of 200 FBs encountered in a hand clinic were missed by the initial physician. Furthermore, missed FBs pose high medicolegal risk for EPs, with one report listing it to be among the top three causes of litigation after wound care.

Most wound FBs are wood, glass, or metal. The upper extremity is the most common location (58%), followed by the lower extremity (36%). The head and neck (4%) and the trunk (1%) are far less common. Most cases will be seen on the day of injury (75%), but some (8.7%) will initially be evaluated weeks, months, or years later.

PATHOPHYSIOLOGY

A retained FB can lay harmlessly dormant for a long period and then can react with surrounding tissue. When a tissue reaction occurs, several sequelae are possible. An infection may occur. The patient’s body may dissolve, extrude, or encapsulate the FB and form a granuloma, and subsequent rupture of the granuloma from minor trauma can cause delayed infection. The extent of tissue reaction depends primarily on the chemical composition of the material. Inert material causes less tissue inflammation, whereas reactive material can cause intense tissue reactions (Box 187.1) and rarely even allergic reactions. Even when an FB does not cause a tissue reaction, it can have other effects. The FB may cause local compression on neighboring structures such as nerves, tendons, joints, or vessels, thereby causing pain or structural damage. Local migration or, more rarely, distant embolization can also occur.

The most threatening FBs are reactive. Wood is especially toxic to soft tissue and virtually always requires removal. FBs causing infection and pain and FBs that are near vital structures such as nerves, tendons, vessels, and joints are also potentially dangerous. Hand FBs tend to migrate locally but rarely embolize, whereas proximal forearm FBs are more likely to embolize.

PRESENTING SIGNS AND SYMPTOMS

The classic example of a wound FB is a patient who sees or knows that foreign material is present in a wound, such as a splinter, glass in the sole of the foot that the patient cannot remove, or an obviously soiled wound. Alternatively, it is also
common for a patient to have a wound and not to know that foreign material is present. The chief complaint of such patients is simply that they have a wound. Certain mechanisms are highly suggestive of wound FBs (Box 187.2). Some unique wound FBs include shrapnel, fishhooks, bullets and BBs, cactus spines, and marine material (Table 187.1). Some patients may exhibit sequelae of a retained FB from the part of the patient can confidently rule in or exclude an FB sensation on palpation. The function of nearby nerves and tendons should also be evaluated.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

No wound is too small or superficial to harbor an FB, and thus the possibility of an FB must be considered for all wounds. Most wound FBs are initially diagnosed by physical examination. The most important aspect of the physical examination is wound exploration. The wound should be explored in a bloodless field, which may require tourniquets or lidocaine with epinephrine infiltration if direct pressure is insufficient. Adequate anesthesia is crucial. The wound should be visualized completely and with range of motion of the involved digit. The wound can be probed with an instrument. Sometimes an FB is detected only by the grating sound of a metal probe against it. Probing the wound with the examiner’s finger exposes the examiner to puncture wounds and should not be done. The wound can be palpated through the skin with two hands, one stationary as a “stabilizer” and the other mobile as a “mover.” Puncture wounds should be palpated for the exquisite tenderness that may be elicited in the presence of an FB. The function of nearby nerves and tendons should also be evaluated.

### BOX 187.2 Scenarios Suggestive of Foreign Bodies in Wounds

- History of stepping on glass
- History of punching through a window
- Motor vehicle collision wounds from glass
- Wounds on the sole of the foot
- Puncture wounds
- Head wounds from glass
- Objects that fragment while in one’s hand
- Fall onto gravel or soil
- Pain at a site of intravenous drug use
- Foot laceration while walking in a stream
- Wound infection, especially if persistent
- Perioral wounds in the presence of broken teeth
- Persistent wound pain
- Failure to heal, persistently draining wound

</table>
examination (78%), but many are diagnosed primarily by imaging studies (22%). Exploration alone is insufficient to rule out an FB, even when the entire wound is thought to be visualized. Therefore, imaging should be used liberally. Selection of the proper imaging modalities requires knowledge of the radiographic properties of the material (Box 187.3 and Figs. 187.1 through 187.3). Even when a suspected FB is not radiopaque, plain film radiographs with an underpenetrated soft tissue technique could be considered because other useful soft tissue or bony findings and reactions may be present. Furthermore, failure to order radiographs has been associated with unsuccessful legal defense in cases of retained FBs. Ultrasound scanning is particularly useful for nonradiopaque FBs (Fig. 187.4). Low-power portable fluoroscopy, when available, is useful to aid in removal of radiopaque FBs. Computed tomography and magnetic resonance imaging are rarely indicated. However, computed tomography may be useful for ocular or periorbital FBs (Table 187.2).

After an FB is diagnosed, the next step is to decide whether to attempt removal or to leave the FB in place. Not all FBs require removal. If an FB is deep, small, inert, away from vital structures, and asymptomatic, attempts at removal may be more destructive than helpful (Box 187.4). Irrigation is an important intervention that not only cleans the wound but also often removes tiny FBs and particulate matter that would otherwise be difficult to localize.

**BOX 187.3 Radiopaque and Nonradiopaque Foreign Bodies**

**Radiopaque Foreign Bodies**
- Glass
- Metal
- Bone
- Teeth
- Pencil tips, graphite
- Gravel

**Nonradiopaque Foreign Bodies**
- Wood (only 15% seen on radiographs)
- Most plastic
- Thorns
- Cactus spines
- Vegetative matter

Fig. 187.1 This patient had a laceration over the olecranon after a motor vehicle collision. A radiograph reveals a foreign body (A). A piece of glass was removed (B).

Fig. 187.2 This patient sustained multiple superficial wounds to the sole of the foot while running barefoot through gravel. A radiograph performed after all gross material was removed revealed two residual foreign bodies (arrows). The bits of gravel were removed.

Fig. 187.3 This patient stepped on broken glass (A). The radiograph, when magnified and scrutinized, showed a possible foreign body (arrow) in the proximity of the wound (B). The wound was explored and a glass foreign body was removed (C). This is an example of the limitations of radiographs for detection of foreign bodies, even those that are radiopaque, in certain locations such as the sole of the foot because of the thickened tissue and multiple bony structures that may obscure the foreign body. This is why wound exploration is also important.
**TREATMENT** (see the “Tips and Tricks” box)

Exploration is best done while the EP is seated comfortably with optimal anesthesia, hemostasis, lighting (even headlamps), and equipment. Fine-tipped forceps, retractors, special pickups, and magnifying loupes are particularly helpful. Many explorations require extending the incision for better exposure. The EP should listen during probing for a grating sound of the FB against the instrument. Blind grasping is destructive to tissue and should be avoided. The use of portable fluoroscopy or ultrasound scanning, if readily available, should be considered to facilitate removal. A time limit for the procedure should be set in advance because it is easy to become involved and determined to recover an FB that may be too difficult to remove in the ED setting. The patient should be aware of this time limit.

Wounds that are contaminated or may still contain FBs should be left open or packed. Antibiotics should probably be prescribed for these patients. EPs should be sure to pad or splint areas with retained FBs before patients are discharged. If all FBs have been removed and the wound has been thoroughly cleansed, closure may be appropriate. An algorithm for an approach to FBs is presented in **Figure 187.5**.

If all FBs have been removed and the wound has been cleaned adequately, the patient is unlikely to require further referral. If concern still exists about a retained FB, the area should be patted or splinted, antibiotics should be prescribed,
and the patient will require consultation or referral to a surgical specialty such as hand, orthopedic, plastic, or general surgery. Such referral can almost always take place on an outpatient basis unless severe infection or important structural damage is present.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Admission is seldom indicated. Admission scenarios may include severe infections and FBs that are going to be removed in the operating room. Documentation and patient education are important aspects of all wound cases. (See the “Documentation”, “Patient Teaching Tips”, “Red Flags”, and “Priority Actions” boxes.)

**TENDON AND NERVE LACERATIONS**

**EPIDEMIOLOGY**

Lacerations are one of the most common chief complaints of patients seen in the ED. It is estimated that a total of

---

**BOX 187.4 Indications for Removal of Foreign Bodies**

Significant pain
Functional impairment, restriction of motion
Reactive material: wood, thorn, other vegetative material, clothing
Cause of infection
Cause of psychologic distress
Contamination: tooth, soil
Toxicity: venomous spines, lead poisoning from bullets
Allergic reaction
Impingement of nerve, tendon, vessel
Intraarticular or periarticular location
Intravascular location
Location near fractured bone
High potential to migrate toward anatomic structures or to embolize
Cosmetic concerns: tattooing, masses

6,400,000 open wounds were treated in EDs in the United States in 2004, thereby making open wounds anywhere on the body the third leading primary diagnosis group. Approximately one third of all open wounds are located on the upper extremity (specifically the fingers, hand, or wrist). An improperly functioning or insensate digit as a result of tendon or nerve injury can lead to markedly impaired function and significant subsequent morbidity. Wound claims, particularly of the hand, are a leading cause of litigation. Although lacerations about the foot and ankle are also relatively common, given the importance and prevalence of hand injuries, this part of the chapter focuses primarily on tendon and nerve lacerations of the hand.

**DOCUMENTATION**

**Soft Tissue Injury**

**History**

Detailed mechanism, hand dominance, timing, type of material, whether the object broke on impact or was already broken, whether the wound was soiled, whether anything was pulled out of the wound, FB sensation, paresthesia, weakness, tetanus immunization status, medical conditions that may impair healing or compromise immune function, intravenous drug use, and persistent pain, infection, or drainage

**Physical Examination**

Position of the hand at rest, detailed neurovascular examination including two-point discrimination, ability to achieve active range of motion and the presence of pain with passive motion, wound size and depth, tenderness, visible contaminants, infection, tattooing, discoloration, signs of infection, and masses

**Studies**

Documentation of radiographic results before and after removal of FBs or any other injuries

**Medical Decision Making**

Reasons to pursue or not pursue FB work-up, factors involved in attempting FB removal or leaving in place, and referral or consultation

Documentation of reasons to refer a surgeon on an outpatient basis and discussion of the case with the referral physician

**Procedures**

Documentation of whether the entire extent of the wound base was visualized in a bloodless field with adequate anesthesia and the tendon was visualized through full range of motion (when appropriate)

**Patient Instructions**

Documentation of discussion with the patient regarding the possibility of a retained FB, tendon or nerve injury, warning signs, what to do, when to return, and when follow-up should occur

FB, Foreign body.

**PATIENT TEACHING TIPS**

Inform patients with wounds of the remote possibility of a missed foreign body because there is no way to truly guarantee that all foreign material has been identified and removed.

After the first couple days, a normal wound should show consistently gradual improvement in pain, swelling, and discoloration.

Inform patients that a retained foreign body may result in persistent pain, loss or impairment of function, a mass, infection, or injury to a nerve, tendon, vessel, or joint. These complications may develop even months or years later.

If any of the foregoing situations develop, the patient should know to return to the emergency department or should have received specialty referral.

Warn the patient to return for signs of infection, including redness, discharge, pain, and swelling.

Warn patients who have documented partial tendon lacerations, depending on the degree of laceration and findings on subsequent examination, that the referring physician may or may not repair the injury.

Inform all patients of the possibility of tendon or nerve lacerations not visualized on examination.

If a nerve or tendon laceration has been documented, ensure that the patient understands the importance of timely follow-up.

**RED FLAGS**

**Complications of Retained Foreign Bodies**

- Infection, possibly recurrent
- Persistent pain
- Functional impairment
- Granuloma formation
- Psychologic distress
- Migration, embolization
- Delayed healing
- Nerve, tendon, joint, vascular injury

**PRIORITY ACTIONS**

**Maintaining a High Index of Suspicion for Foreign Bodies in All Wounds**

- Appropriate use of imaging
- Wound exploration
- Decision whether to attempt removal of the foreign body in the emergency department
- High-pressure irrigation, wound cleansing
- Appropriate use of antibiotics
- Specialty referral, consultation for retained foreign bodies
- Proper discharge instructions
PATHOPHYSIOLOGY

The hand is one of the most multifaceted and complex musculoskeletal systems in the body. The precision and fine motor functions of the hand are a direct result of its intricate structure. The frequency and importance of hand injuries necessitate that EPs have a thorough understanding of the anatomic and functional complexity of the hand.

The nerve supply to the hand is provided by the radial, ulnar, and median nerves. The radial nerve is purely sensory in the hand (motor function of the radial nerve includes wrist extension). The median and ulnar nerves provide the entire motor function of the hand and some sensory function as well (Fig. 187.6). Each digit has two neurovascular bundles located near the palmar aspect of the finger, one on the radial side and the other on the ulnar side.

The extensor tendons are located on the dorsal surface of the forearm, wrist, and hand. Nine extensor tendons pass under the extensor retinaculum. The extensor tendons join to become the extensor expansion and then separate into six fibroosseous compartments. In each digit, the extensor expansion then divides into a central slip attaching to the middle phalanx and two lateral bands joining with the tendons of the lumbricals and then continuing on to attach to the base of each distal phalanx. See Figure 187.7 for extensor tendon zone classification.

The flexor tendons are located on the volar side of the forearm, wrist, and hand. A single tendon (the flexor pollicis longus) inserts on the distal phalanx of the thumb, and two flexor tendons go to each of the remainder digits. Each digit has a superficial flexor tendon that inserts at the base of the middle phalanx and a deep flexor tendon that inserts at the base of the distal phalanx.

The superficial location of the tendons and nerves of the hand combined with the lack of overlying subcutaneous tissue predisposes these structures to injury. Injuries to the tendons have been grouped into anatomic zones for easy understanding and classification. The most widely accepted classification system is that of Verdan. This system uses eight zones, from zone I at the distal interphalangeal joint level to zone VIII at the distal forearm level. This system has been modified to five zones for the flexor tendons (Fig. 187.8). Although the Verdan system is no longer used to determine treatment options, knowledge of the zones is useful for prognosis.
PRESENTING SIGNS AND SYMPTOMS

Any patient with a laceration about the hand or wrist may have sustained a tendon or nerve laceration regardless of how superficial the wound may appear. In a study of 226 patients with upper extremity lacerations that were less than 2 cm in length, 59% were found to have at least one injury to a deep structure.16 Depending on the degree of injury, the patient may have no obvious injury other than a laceration through the skin.

Patients with nerve lacerations typically have a complaint of numbness or tingling distal to the laceration. In cases of injury to the radial, ulnar, or median nerves, the corresponding motor distribution is affected. Unless a motor deficit is noted, the clinical finding of a nerve injury may easily be missed.

The normal resting position of the hand—flexed fingers, with the little finger having the greatest degree of flexion and the index finger the least—may be altered in patients with a complete tendon laceration (Fig. 187.9). Flexor tendon disruption is indicated when the injured finger lies in complete extension while the others are in slight flexion. When the patient has an extensor tendon injury, the affected digit is held in full flexion while the others are held in slight extension or the normal position of function. Partial lacerations may not be evident based on the position of the finger. Limited or painful movement, especially if more severe than would be expected with the laceration, suggests partial tendon involvement.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

The most important aspects of the diagnosis of tendon or nerve laceration are a thorough history and physical examination. Basic historical details should include the time and mechanism of injury, position of the hand when injured, hand dominance, tetanus status, previous hand injuries, and occupation and hobbies (musician or anyone requiring fine motor control). Patients should be specifically asked about loss of motion, weakness, pain, and any numbness or tingling.

Examination of the hand begins with an overall assessment of the position of the hand and fingers. Pallor, gross deformity, or digits lying in abnormal positions should be noted and compared with the other fingers and hand. Next, the sensation and motor strength of the hand should be assessed to detect nerve injury. As stated previously, the radial, ulnar, and median nerves provide sensation to the hand. Because of the overlap in sensory innervation, it is best to test nerves in the area least likely to have dual innervation. The median nerve is tested at the palmar surface of the index finger, the ulnar nerve at the palmar surface of the little finger, and the radial nerve at the dorsal surface of the web space between the thumb and index finger.

Various stimuli can be used to test sensory function of the hand. Gross touch with a blunt object is the least specific. It can be useful for rapid screening to test for nerve injury, especially when compared with the other hand. A more accurate method for assessing nerve function is two-point discrimination. A paper clip can be used. A patient with a normally innervated fingertip should be able to distinguish two simultaneously delivered stimuli 6 mm or more apart from each other. Most patients can detect a difference down to 3 mm. When identification of stimuli separated by 8 mm or more is not reported by the patient, the examination is clearly abnormal.

Accurate evaluation of two-point discrimination to assess for nerve injury is not always possible at the time of injury. The patient’s pain and anxiety, as well as factors such as the presence of hand calluses, can interfere with this test. Any subjective “numbness” reported by the patient must be taken seriously, and consultation with a hand specialist should be considered. Under these circumstances, it is common to close the skin wound and refer the patient for evaluation within a few days of the initial injury.

A systematic examination of the hand and wrist includes assessment of active and passive range of motion of the wrist and digits. To check specifically for extensor tendon injuries, the patient should actively extend each finger and then extend each finger against resistance. In evaluating the flexor tendons, the superficialis and profundus tendons should be tested independently, with the patient actively flexing individual proximal and distal interphalangeal joints (Fig. 187.10). Examiners

---

**Fig. 187.9** Examination to assess the function of the flexor digitorum superficialis. (From Lyn E, Antosia RE. Hand. In: Rosen’s emergency medicine. 6th ed. Philadelphia: Mosby; 2006. p. 576-621.)

**Fig. 187.10** To test for an intact profundus tendon, the examiner maintains the digit in extension while the patient attempts to flex the terminal phalanx. (From Lyn E, Antosia RE. Hand. In: Rosen’s emergency medicine. 6th ed. Philadelphia: Mosby; 2006. p. 576-621.)
should be sure to check tendon motion against resistance because patients with partial tendon lacerations may have normal range of motion.

The next step is exploration of the wound (Fig. 187.11), which is best done with the EP seated comfortably with optimal anesthesia, hemostasis, lighting, and equipment. Adequate anesthesia is crucial. Failure to provide adequate exposure of deeper wound structures because of the patient's discomfort often leads to missed injuries. The wound should be explored in a bloodless field. A tourniquet may be required if direct pressure is insufficient to achieve such a field. The wound should be visualized completely and with full range of motion of the involved digit.

Additional studies or imaging techniques are indicated to evaluate for FBs, fractures, and avulsions. They are not useful in evaluating tendon or nerve lacerations. Ultrasonography may be a viable diagnostic tool in evaluating tendon injuries, although at this time it has not been studied in the ED.17

**TREATMENT**

All motor branches of the ulnar and median nerve should be repaired. Both consultation in the ED and referral the following day after discussion with the referring physician are appropriate (Box 187.5). Digital nerve injuries proximal to the distal interphalangeal crease on the radial aspect of the index and middle fingers, the ulnar side of the little finger, and both sides of the thumb should be repaired. The timing of repair for simple, clean nerve injuries is somewhat controversial; some data show better results with repair in 6 to 12 hours, whereas other data show acceptable results with delayed repair.18 Satisfactory return of function can occur after nerve repair or a graft performed within 3 months of injury.19 Any patient with a suspected nerve injury should be referred to a specialist for evaluation and possible repair.

Patients with tendon lacerations (partial or complete) require early referral to a surgeon. Most surgeons recommend repairing complete lacerations primarily within 12 to 24 hours after the injury. However, data on delayed primary (<10 days) or early secondary (2 to 4 weeks) repair show little difference in outcomes when compared with the traditional immediate repair.20 Repair of partial tendon lacerations is still controversial, and most hand surgeons now repair only lacerations that involve more than 50% of the tendon surface. Regardless of whether the laceration is full or partial, primary coverage of the injured tendon by skin suturing after wound irrigation protects the tendon and retards infection, but it should be undertaken only after consultation with the specialist who will perform the definitive repair.

Extensor tendon injuries are underestimated by EPs. Because of the superficial location and thin overlying subcutaneous tissue, these tendons are often injured. Their superficial location makes repair easier; in the past these injuries have been repaired by EPs, although it is generally best to coordinate with a surgeon willing to provide repair and follow-up. Zones VII and VIII are associated with significant retraction of tendons, and given the proximity of many tendons, multiple tendons may be injured. Therefore, injuries to tendons in these zones are more difficult to repair and may have worse outcomes.

Flexor tendon injuries are more difficult to repair. These injuries are more complicated because both superficial and deep tendons are present and both may be injured. Injuries in zones II and IV have a much worse prognosis as a result of the propensity to form adhesions within a confined space. Overall, ED consultation with a specialist or early referral after discussion with the specialist who will perform the definitive repair should be ensured for any confirmed nerve or tendon injury (extensor and flexor), overlying lacerations involve more than 50% of the tendon surface. Regardless of whether the laceration is full or partial, primary coverage of the injured tendon by skin suturing after wound irrigation protects the tendon and retards infection, but it should be undertaken only after consultation with the specialist who will perform the definitive repair.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

Most patients with tendon and nerve lacerations can be discharged home safely from the ED. Educating the patient regarding expectations and the importance of follow-up is of utmost importance. All patients with documented or suspected lacerations of a tendon or nerve require evaluation by the appropriate surgeon. ED consultation and early referral following discussion with a specialist are both appropriate.
courses of action. If severe infection or important structural damage is present, ED consultation may be more prudent than outpatient follow-up. The area should be splinted appropriately and antibiotics prescribed if indicated. Flexor injuries should be splinted with the wrist in 30 degrees of flexion, the metacarpophalangeal joints flexed 70 degrees, and the interphalangeal joints flexed 10 to 15 degrees. A metal protective splint is recommended for patients who are going to return to work. All but very minor hand wounds are best followed up within 48 hours for removal of the dressing and inspection of the wound for signs of infection. (See Box 187.6 for complications.)

Local and Regional Anesthesia
Heather Murphy-Lavoie and Tracy Leigh LeGros

**KEY POINTS**

- Alternatives to local infiltration for anesthesia include topical anesthesia and regional nerve blocks.
- Comfortable wound repair requires adequate anesthesia.
- Local infiltration may be inadequate or suboptimal in certain situations.
- For the safety and efficacy of regional anesthesia, the clinician must have a detailed understanding of the local anatomy.
- Ultrasound is a very useful adjunct to regional anesthesia.

**PERSPECTIVE**

Adequate anesthesia is essential for many situations in the emergency department (ED), such as acute wound repair, removal of foreign bodies, drainage of abscesses, removal of ingrown toenails, joint reductions, and management of fractures. To achieve anesthesia safely and accurately, the clinician must have a thorough understanding of the various agents that can be used, the methods of administration, and the techniques for achieving regional anesthesia.

**SELECTION OF ANESTHETIC AGENTS**

**MECHANISM OF ACTION**

Local anesthetics usually have an aromatic ring structure connected to a tertiary amine by either an ester or an amide link. This link determines the class of the agent, ester or amide. Local anesthetics work by reversibly binding to and blocking neuronal sodium channels, thereby blocking conduction of the nerve impulse. Their potency, onset, and duration of action are determined by their ability to access and bind these sodium channels. The higher the lipid solubility, the higher the potency of the anesthetic. The higher their protein binding, the longer the duration of action. Onset of action is determined by the $pK_a$, or the pH at which the agent exists in equal amounts of its ionized and un-ionized forms. The closer the $pK_a$ is to physiologic pH, the faster the onset of action. Most local anesthetic agents are associated with a burning sensation that lasts several seconds before the onset of anesthesia. Patients should be warned of this sensation before administration (Table 188.1).

**TOXICITY**

Local anesthetic agents exert toxic effects primarily on the cardiovascular system and central nervous system (CNS). The severity of toxicity is directly related to lipid solubility and therefore the potency of an agent. Accordingly, bupivacaine is much more likely than lidocaine to cause toxicity. The likelihood of toxicity also rises with increased vascularity and systemic absorption. Absorption rates by anatomic location, from highest to lowest, are as follows:

- Intercostal
- Intratracheal
- Epidural
- Brachial plexus
- Mucosal
- > > > >
- Distal peripheral nerve
- Subcutaneous

An intercostal block has the highest potential for toxicity; therefore, the maximum amount of anesthetic agent recommended for this location is only one tenth of the maximum for peripheral nerve blocks. All sites are associated with a certain degree of risk, especially when accidental intravascular injection is likely.

Signs of CNS toxicity with local anesthetics are presented in Box 188.1.

If exposure is not halted, toxicity can progress to seizures, coma, respiratory depression, and cardiorespiratory arrest. Higher doses result in cardiovascular toxicity and lead to tachycardias, sinus arrest, atrioventricular dissociation, hypotension, and full arrest. Premedication with benzodiazepines may blunt the CNS toxicity, and in these cases the first sign of toxicity to develop may be cardiovascular collapse.

Amides are metabolized by the liver, and patients with hepatic dysfunction may be predisposed to systemic toxicity. Esters are metabolized by plasma pseudocholinesterase, and therefore patients with pseudocholinesterase deficiency, such as those with myasthenia gravis, are at higher risk for systemic toxicity. In addition, metabolites of prilocaine (a component of EMLA cream) and benzocaine have been associated with methemoglobinemia.
**SYSTEMIC AGENTS**

**Lidocaine**
Lidocaine is the most commonly used local anesthetic agent. Its low cost, rapid onset, duration, and toxicity profile make it ideal for most routine applications. The maximum dose of lidocaine is 4 to 4.5 mg/kg (e.g., a 70-kg patient should receive no more than 300 mg, or 30 mL of a 1% solution). The maximum dose may be increased to 7 mg/kg when lidocaine is given with epinephrine but will also cause an increase in sympathomimetic side effects (tachycardia and hypertension) and a theoretically higher risk for infection because of diminished blood supply to the affected area. The pain of injection can be reduced either by warming lidocaine to body temperature before administration or by buffering it with sodium bicarbonate (1 mL sodium bicarbonate to 9 mL of 1% lidocaine).²⁻⁴

**Mepivacaine**
Mepivacaine is structurally similar to lidocaine and has a similar onset of action and a slightly longer duration. As with bupivacaine, this longer duration of action is associated with a slightly higher risk for toxicity. The toxicity of mepivacaine is between that of lidocaine and bupivacaine, which corresponds to its intermediate duration of action.

**Tetracaine**
Tetracaine is an ester agent. It is most commonly used in the ED for corneal anesthesia and as a component of LET (lidocaine 4%, epinephrine 0.1%, tetracaine 0.5%).

**Ropivacaine**
Ropivacaine is a relatively new amide local anesthetic that was approved by the U.S. Food and Drug Administration (FDA) in 1996. Being the S-isomer of bupivacaine, ropivacaine is very similar in terms of onset of action, is slightly less potent, has a slightly shorter duration of action, and is associated with a 70% lower likelihood of cardiac toxicity. It also costs almost twice as much as bupivacaine.

**Bupivacaine**
Bupivacaine is slightly more potent than lidocaine and lasts longer, but its onset of action is delayed. The maximum dose of bupivacaine is 2.5 mg/kg (e.g., a 70-kg patient should receive no more than 175 mg, or 35 mL of a 0.5% solution), which can be increased to 3 mg/kg if this agent is given with epinephrine. The high potency and protein binding of bupivacaine increase its risk for systemic toxicity when compared with lidocaine.

**ALLERGIC REACTIONS**
True allergic reactions to local anesthetics are relatively rare. They are usually secondary to the preservative rather than to the agent itself. If an allergy is reported but not verified, the emergency physician should consider using a preservative-free agent, such as cardiac lidocaine from the “code” cart. Other options include switching classes (allergy to esters is more common than allergy to amides, and cross-reactivity is common within the class) or using benzyl alcohol,⁶ diphenhydramine,⁷ ice, or normal saline injection. An easy way to determine the class of an agent is to remember that all amides with two i’s in their names and the esters only have one. If a patient is truly allergic to lidocaine, none of the anesthetic agents with two i’s should be used (diphenhydramine is an exception to this rule of thumb because it is not classically considered an anesthetic agent).

TOPICAL AGENTS

**Lidocaine, Epinephrine, and Tetracaine**

LET (lidocaine 4%, epinephrine 0.1%, tetracaine 0.5%) is an excellent and safe topical anesthetic agent. It can be premixed by the hospital pharmacy and stored in the refrigerator for use in the ED. It is applied to wounds by soaking a cotton ball in LET and then securing the cotton ball to the wound for 15 to 30 minutes. Blanching of the skin around the wound indicates adequate anesthesia. Additional injected anesthetic may be required, but its application should be much more comfortable for the patient after LET pretreatment. LET (or any mixture containing epinephrine) should, by convention, not be used on the ear, nose, penis, or digits because of its vasoconstrictor effects.8,9

**EMLA**

EMLA (eutectic mixture of local anesthetics: 2.5% lidocaine and 2.5% prilocaine) is approved by the FDA only for use on intact skin, although successful use in open wounds has been reported in the medical literature. Approximately 1 hour of topical application of EMLA is required to achieve local anesthesia, a characteristic that limits its usefulness in emergency cases. Infants younger than 3 months are at theoretically higher risk for the development of methemoglobinemia from EMLA because of inadequate levels of methemoglobin reductase.8,9

**Liposomal Lidocaine**

ELA-Max is a relatively new proprietary mixture of 4% liposomal lidocaine that has been approved by the FDA for the temporary relief of pain from minor cuts and abrasions. Its onset of action is much shorter than that of EMLA (only 30 minutes), and it carries a much lower risk for methemoglobinemia because it does not contain prilocaine. This formulation may replace EMLA for most topical indications.8,9

REGIONAL NERVE BLOCKS

**INDICATIONS**

Regional nerve blocks are used for areas that are not amenable to local infiltration, such as the palms, the soles, and the fat pads of fingers and toes. Other advantages are avoidance of local tissue distortion and the ability to anesthetize large areas with fewer injections and less anesthetic agent. This reduces both the likelihood of toxicity and overall discomfort to the patient. Specific examples of common indications for regional nerve blocks are drainage of paronychia or felon; treatment of hand, foot, ear, and digit lacerations; débridement of road rash; treatment of nail bed injuries and ingrown toenails; and dental extraction. Regional nerve blocks also alleviate the pain associated with long-bone fractures and joint dislocations. Ultrasound guidance is recommended for injections into deep structures, such as femoral and scalene nerve blocks.

**GENERAL TECHNIQUE**

The physician should explain the procedure to the patient and obtain consent (after carefully documenting any known allergies). The procedure is performed as follows:

1. Prepare the skin with povidone-iodine or other antiseptic skin solution.

2. Identify the area’s landmarks.

3. Induce a superficial skin wheal at the injection site to reduce the discomfort of further manipulation.

4. Advance the needle to the target area while asking the patient to report any paresthesias.

5. If the patient does report paresthesias, thus indicating that the needle is within the nerve sheath, withdraw the needle 1 to 2 mm, aspirate to ensure that the needle is not in a vessel, and inject the agent slowly.

The agent of choice is usually lidocaine. Bupivacaine may be preferable when longer duration of action is desired.
aspiration is performed to verify that the needle is not in a vessel, and 5 mL of anesthetic agent is injected slowly as the needle is withdrawn.

**Ulnar Nerve**
The ulnar nerve provides sensation to the palmar surface of the ulnar half of the hand and the fourth and fifth fingers (see Fig. 188.1). The ulnar nerve travels very close to the ulnar artery, deep to the flexor carpi ulnaris, so extra care must be taken to avoid intraarterial injection. The landmarks for this block are the flexor carpi ulnaris and the proximal wrist crease (see Fig. 188.2). The patient should be instructed to flex the wrist, and the operator should palpate the tendon proximal to the pisiform. With the lateral approach, the needle is advanced 1 to 1.5 cm horizontally under the flexor carpi ulnaris tendon, aspiration is performed to ensure that the needle is not located intraarterially, and 5 mL of anesthetic agent is slowly injected while the needle is withdrawn.

The ulnar nerve also gives off several subcutaneous branches that travel from the lateral border of the flexor carpi ulnaris to the dorsal midline. These branches are blocked by subcutaneous injection of an additional 5 to 10 mL in a superficial ringlike wheal from the lateral aspect of the proximal wrist crease to the dorsal midline (see Fig. 188.2).

**Radial Nerve**
The radial nerve provides sensation to the dorsal radial aspect of the hand and the first through third digits (see Fig. 188.1). The radial nerve travels lateral to the radial artery at the wrist and gives off superficial cutaneous branches that travel laterally to the dorsal midline. The landmarks for this block are the proximal wrist crease and the radial pulse (see Fig. 188.2). The needle is inserted perpendicularly, just lateral to the radial pulse and 1 to 2 mm below the depth of the artery. Aspiration is performed and 3 to 5 mL of anesthetic agent is injected as the needle is slowly withdrawn. The subcutaneous branches are blocked with a superficial ringlike wheal, starting at the initial injection site and tracking to the dorsal midline (see Fig. 188.2).

**Digital Nerves**
Each finger has two sets of nerves, called the dorsal and palmar digital nerves, that travel in the 2-, 4-, 8-, and 10-o’clock positions around the digit (Fig. 188.3). These four branch form two root nerves at the metacarpal-metatarsal heads. The most common approach for a digital nerve block is the proximal-most aspect of the finger or toe, where the nerves travel in the most consistent path. A skin wheal is formed on the dorsal surface of the finger or toe. The needle is then directed to the 2-, 4-, 8-, and 10-o’clock positions, respectively. After aspiration is performed, 0.5 to 1 mL of agent is injected at each site. Epinephrine and other vasoconstricting agents should not be used in this location because of the risk for critical ischemia.

**Interscalene Nerve**
An ultrasound-guided interscalene nerve block is a useful method of inducing anesthesia for shoulder dislocations and is especially useful in patients who have a contraindication to procedural sedation or high opiate tolerance. Deep to the sternocleidomastoid muscle on the lateral anterior aspect of the neck is where the anterior and middle scalene muscles lie. The interscalene nerve bundle appears between the anterior and middle scalene muscles and has the appearance of three small round pealike structures (Fig. 188.4). Under direct visualization with ultrasound, 30 mL of 1% lidocaine should be
injected adjacent to the nerve bundle. Use of a 20-gauge spinal needle is recommended because its noncutting nature may be less likely to result in nerve laceration. Of note, it is important to visualize the needle tip throughout the entire procedure to ensure proper positioning and avoid damage to surrounding structures. After approximately 10 to 30 minutes, shoulder anesthesia should allow painless reduction. Temporary paralysis of the hemidiaphragm will occur and is usually asymptomatic; however, this procedure would be contraindicated in anyone who cannot tolerate a 30% reduction in pulmonary function. Occasionally, the cervical sympathetic chain may be affected and result in hoarseness and Horner syndrome. Patients should be advised of these possibilities when consent is obtained for the procedure.

**Bier Block**

A Bier block involves the intravenous injection of a regional anesthetic into an extremity on which a tourniquet has been placed. Its use is relatively uncommon in the ED, but its advantage is the concomitant creation of a bloodless field. Peripheral intravenous access should be established in the target extremity at least 10 cm distal to the tourniquet. In addition, access should be established in a backup extremity in the event that access for resuscitation is needed. Because of its safety profile, 0.5% lidocaine without epinephrine is the agent of choice. This can be mixed by dilution of 1% lidocaine with an equal part of normal saline. The usual dose is 1.5 to 3 mg/kg.

A pneumatic tourniquet is applied over cotton padding proximal to the injury on the arm. The arm is elevated for at least 3 minutes to exsanguinate it before inflation of the tourniquet. With the arm elevated, the cuff is inflated to 250 mm Hg (or in a child, to 50 mm Hg greater than systolic pressure). The extremity is then lowered, and the agent is injected slowly. Onset of action is 3 to 5 minutes. Tourniquet time should be monitored carefully and should not exceed 1 hour. If the procedure is brief, the tourniquet should be left in place for at least 30 minutes after injection of the anesthetic to avoid a systemic bolus and higher risk for toxicity.

At the completion of the procedure and waiting period, the tourniquet should be deflated for 5 seconds and reinflated for 1 to 2 minutes; this cycle should be repeated three or four times to ensure slow release of the anesthetic into the systemic circulation. The patient should then be monitored for at least 30 minutes for signs of toxicity.

**LOWER EXTREMITY BLOCKS**

### Femoral Nerve and Three-in-One Block

The femoral nerve block and the three-in-one block (femoral, obturator, and lateral femoral cutaneous nerves) are useful for patients with fractures of the femur or hip. In view of the proximity of the femoral artery and vein to the target nerve, careful palpation of the pulse and aspiration are crucial to the safety of this procedure. Ultrasound can greatly improve the safety and accuracy of this procedure and has been shown to reduce the need for opiate analgesia and the amount of anesthetic required.11 (Fig. 188.5). The landmarks for this procedure are the inguinal ligament and the femoral artery. The femoral artery is palpated 1 to 2 cm distal to the inguinal ligament. The operator’s nondominant hand is kept on the femoral pulse throughout the procedure to reduce the likelihood of intraarterial injection, especially if ultrasound is not being used to visualize the injection. With a perpendicular and slightly cephalad approach, the needle is inserted 0.5 to 1 cm lateral to the pulse until paresthesias are elicited, the patella moves involuntarily, or the needle begins to pulsate laterally. To anesthetize only the femoral nerve, 10 to 20 mL of agent should be injected. To anesthetize all three nerves, 30 mL of agent should be injected in a cephalad direction into the femoral sheath while distal pressure is maintained to ensure proximal tracking of the anesthetic agent.13

### Sural Nerve

The sural nerve supplies sensation to the heel and lateral aspect of the foot (Fig. 188.7). Landmarks for this block are the lateral malleolus and the Achilles tendon (see Fig. 188.7). The needle is inserted just lateral to the Achilles tendon, 1 cm above the lateral malleolus, and directed toward the fibula. When contact with the fibula is made, the needle is withdrawn 1 mm, aspiration is performed, and 5 mL of agent is injected as the needle is withdrawn slowly.

### Peroneal Nerves (Superficial and Deep)

The superficial peroneal nerve supplies sensation to the dorsum of the foot and toes, whereas the deep peroneal nerve supplies the first web space (see Fig. 188.7). The landmarks for these blocks are the extensor hallucis longus tendon, the anterior tibialis tendon, and the anterior lip of the tibia (see Fig. 188.8). The superficial peroneal nerve travels anteriorly between the extensor hallucis longus tendon and the lateral malleolus. The deep peroneal nerve travels under the extensor hallucis longus tendon. For a superficial peroneal nerve block, the needle is inserted just lateral to the hallucis longus tendon and is directed toward the lateral malleolus. The agent is injected in a ringlike fashion from the extensor hallucis longus to the lateral malleolus. For a deep peroneal nerve block, the needle is inserted between the anterior tibialis tendon and the extensor hallucis longus tendon, 1 cm above the base of the medial malleolus, and directed 30 degrees laterally under the tendon. The needle is advanced until it touches the tibia (less than 1 cm) and then withdrawn 1 mm, and 5 mL of agent is injected while the needle is slowly withdrawn.

### Saphenous Nerve

The saphenous nerve provides sensation to the medial aspect of the foot and the arch (see Fig. 188.7). The landmarks for this block are the medial malleolus and the anterior tibialis tendon (see Fig. 188.8). The patient is instructed to dorsiflex the foot to enable the anterior tibialis tendon to be located at the anterior lip of the tibia. The saphenous nerve travels superficially between the anterior tibialis tendon and the medial malleolus. The needle is inserted at the anterior lip of the distal end of the tibia, just lateral to the tibialis tendon, and directed toward the medial malleolus. Five milliliters of agent is injected subcutaneously, in a ringlike fashion, from the anterior tibialis tendon to the medial malleolus.

### Posterior Tibial Nerve

The posterior tibial nerve supplies sensation to the distal two thirds of the plantar surface of the foot (see Fig. 188.7). The landmarks for this block are the medial malleolus, the posterior tibial artery, and the Achilles tendon (see Fig. 188.8). The

Fig. 188.7 Sensory nerve distribution of the ankle.
needle is inserted just anterior to the Achilles tendon at a level 1 cm above the medial malleolus. The needle is directed just posterior to the posterior tibial artery toward the posterior aspect of the tibia. It is advanced until it hits the tibia and is then withdrawn 1 mm. Five milliliters of agent is then injected while the needle is slowly withdrawn.

**FACIAL AND ORAL BLOCKS**

**Supraorbital Nerve**
The supraorbital nerve exits the supraorbital notch along the supraorbital rim. Along with the supratrochlear and infratrochlear nerves, it supplies sensation to the forehead (Figs. 188.9 and 188.10). For a nerve block, the supraorbital notch is palpated, and 1 to 3 mL of agent is injected at this location. If inadequate anesthesia is obtained, a subcutaneous wheal is made down the supraorbital rim with 5 mL of agent to anesthetize branches of the supratrochlear and infratrochlear nerves. Placing a finger just below the eyebrow decreases the incidence of eyelid swelling.²

**Infraorbital Nerve**
The infraorbital nerve exits the infraorbital foramen and branches into the superior alveolar nerves supplying sensation to the midface region (see Figs. 188.9 and 188.10). The intraoral approach is recommended. While holding one finger externally over the inferior border of the infraorbital rim, the physician inserts the needle into the labial mucosa, opposite the apex of the first premolar. The needle is advanced parallel to the long axis of the tooth until it is palpated near the foramen. After aspiration, 2 to 3 mL of agent is injected slowly near but not into the foramen.

**Anterior Superior Alveolar Nerve**
The anterior superior alveolar nerve supplies sensation to the ipsilateral central and lateral incisors, as well as the canine tooth and half the upper lip (see Fig. 188.10). For block of this nerve, the needle is inserted with the bevel facing bone, superior to the apex of the canine, and directed to the canine fossa. After aspiration, 2 mL of agent is injected (see Fig. 188.10).
The posterior superior alveolar nerve provides sensation to the ipsilateral maxillary molars (see Fig. 188.10). After the cheek is retracted laterally, the needle is inserted into the mucosal reflection, just distal to the distal buccal root of the upper second molar. The needle is advanced 2 to 2.5 cm along the curvature of the maxillary tuberosity, at which point 2 to 3 mL of agent is injected to effect a nerve block. The operator should beware of the pterygoid plexus and must perform aspiration before making an injection.

**Middle Superior Alveolar Nerve**

The middle superior alveolar nerve provides sensation to the ipsilateral premolars and sometimes the first maxillary molars (see Fig. 188.10). For a block of this nerve, the needle is inserted with the bevel facing bone, superior to the apex of the upper second premolar tooth, and 2 mL of agent is injected.

**Inferior Alveolar Nerve**

The inferior alveolar nerve supplies sensation to the ipsilateral mandibular teeth, lower lip, and chin (see Figs. 188.9 and 188.10). The coronoid process of the mandible is palpated, and the cheek is retracted laterally. A triangle is visualized in this triangle, 1 cm above the occlusal surface of the molars, and advanced until it contacts the mandible. The needle is retracted slightly, aspiration is performed, and 2 mL of agent is injected slowly. If the needle does not contact the mandible and is directed posteriorly toward the parotid gland, temporary Bell palsy may be elicited if the facial nerve is unintentionally anesthetized. Injection of more agent while the needle is withdrawn will anesthetize the lingual nerve as well.

**Mental Nerve**

The mental nerve branches off the inferior alveolar nerve to supply sensation to the ipsilateral part of the chin (see Figs. 188.9 and 188.10). This nerve emerges from the mental foramen inferior to the second premolar (see Fig. 188.10). For a mental nerve block the foramen is palpated, and then through an intraoral approach, the needle is inserted with the bevel facing bone, superior to the apex of the upper second premolar tooth, and 2 mL of agent is injected.

**FACTS AND FORMULAS**

The names of all amide anesthetic agents contain two i’s. The maximum dose of lidocaine is 4.5 mg/kg without epinephrine and 7 mg/kg with epinephrine. One milliliter of a 1% solution of lidocaine contains 10 mg of lidocaine.
mucobuccal fold and advanced until it can be palpated over the foramen. After aspiration is performed, 1 to 3 mL of agent is slowly injected.

**Nerve Block of an Individual Tooth (Supraperiosteal Block)**

The operator can block the nerve of a single tooth by having the needle enter the mucobuccal fold with the bevel facing bone and injecting 1 to 2 mL of agent at the apex of the tooth, close to the periosteum. It may take longer than most blocks to achieve complete anesthesia because the agent has to penetrate the cortex of the bone to reach the nerve root (5 to 10 minutes).

**Ear Block**

Because several different nerves supply sensation to the ear, an ear block requires a superficial skin wheal around the entire anterior and posterior auricular aspect of the face and scalp (see Fig. 188.10).

**MISCELLANEOUS NERVE BLOCKS**

**Intercostal Nerve Block**

An intercostal nerve block is perhaps one of the most dangerous nerve blocks because of greater systemic absorption of agent injected in this area and a 1.4% incidence of pneumothorax. However, significant pain relief from rib fractures can be obtained with this method. In most cases, opiate analgesia is probably a safer method of pain control. The injured rib is palpated posterior to the posterior axillary line, and the skin is retracted superiorly over the rib. The needle is inserted 5 mm over the rib, the retracted skin released, and the needle walked gently down the inferior edge of the rib. The needle is then advanced 2 to 3 mm, aspiration is performed, and 2 to 5 mL of agent is injected. If pain control is inadequate, this procedure can be repeated for two ribs above and two below the injured area (Fig. 188.11).

**Hematoma Block**

The hematoma of a fracture can be locally anesthetized to relieve the pain associated with relocation of a displaced fracture. This block is most commonly used for metacarpal fractures. Two milliliters of agent is usually sufficient. In this case, if aspiration of blood confirms placement of the needle within the hematoma, care should be taken to avoid anatomic locations of known vessels (Fig. 188.12).

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

Many patients who initially appear to have a mild airway burn injury still require early intubation because critical edema will develop. Intubate; do not observe.

- Extremely high doses of narcotics (three to five times normal) are usually required to control pain in patients with severe burns.
- Patients with severe burns have large fluid requirements, which are best determined initially by standard calculations.
- The best measure of adequate fluid replacement is urine output.
- Cold water can help relieve the pain of first- and second-degree burns, but patients with significant burns involving more than 9% of their total body surface area should not have cold applied.
- Burn centers have improved mortality rates, so transfer to a burn center should be considered early in the patient’s management.
- Empiric oral or intravenous antibiotic administration is not indicated, but topical antibiotics are.

**EPIDEMIOLOGY**

Approximately 500,000 patients sustain nonfatal burn injuries in the United States each year. Only 6% of these patients require hospitalization, so most are treated as outpatients.

Serious burns are some of the most challenging critical care cases. Approximately 8% of all burns result in death. Furthermore, care must be optimized because long-term disability can be moderated if initial resuscitation is adequate, infections are minimized, and specialty care by burn experts is promoted.

**PATHOPHYSIOLOGY**

Knowing the anatomy of the skin is essential to understanding burn pathophysiology (Fig. 189.1). Burns are classified according to the depth of injury (Table 189.1 and Fig. 189.2). First- and second-degree burns are partial-thickness burns and have a better prognosis. Full-thickness burns (third and fourth degree) are insensate and require skin grafts (unless <1 cm) or reconstruction because of destruction of the epidermis and dermis. Based on the depth of the burn, the ability to heal can be predicted. Because the dermis itself is the living tissue, the depth of burn into the dermis determines how likely wounds are to heal and what degree of scarring can be expected.

The severity of the burn depends on the duration of contact with the burn agent, the heat and conductivity of tissues, the heat of the burn agent, heat transfer (conduction, convection, or radiation), and the heat capacity of the burn agent.

Burns damage by two methods: first, by direct injury to the cellular structure of the tissue and, second, by the release of local mediators. Three zones are discussed with burn injuries: the zone of coagulation, the zone of stasis, and the zone of hyperemia. The zone of coagulation is the necrotic area of cell death as a result of direct thermal injury. Surrounding this area is the zone of stasis, which has decreased blood flow and is at risk for cell death within 24 hours but may initially appear as living tissue. Cell mediators such as thromboxane A2 are predominantly responsible for transforming this area into the zone of coagulation. Outside this zone is the zone of hyperemia. The zone of hyperemia is defined as the outside area of tissue affected by the burn, usually blanching on touch, but with intact blood flow and high potential to recover from the initial insult.

The secondary effects of burns, such as histamine release and edema, are thought to result from cellular mediators. Aggregated platelets from the burn release serotonin, whereas histamine is derived from mast cells within the burned skin.

**PRESENTING SIGNS AND SYMPTOMS**

Frequently, occupational exposure causes burns. Direct contact with flame, scalds, injuries caused by heated equipment or arc welding, gasoline fires, and cooking accidents are all common. In children or elderly patients with burn injuries, the concern for abuse is always present (see the “Red Flags” box).

**RED FLAGS**

- Burns inconsistent with the mechanism: concerning for non-accidental trauma or abuse
- Circular burns consistent with cigarette butt burns
- Burns on the lower extremities without burns on the soles: consistent with forced immersion scald burns
- Any perineal burn (area not exposed during normal activities)
Fig. 189.1 Schematic representation of a cross section of human skin. The two major layers of human skin, the epidermis and the dermis, overlie subcutaneous fat and muscle. Arterioles (red), venules (blue), and lymph vessels (yellow) of the dermis form a lower and an upper vascular plexus. Capillary loops extend toward the epidermis from the upper plexus of blood vessels into the dermal papillae, approximately one loop per dermal papilla. Sensory and autonomic nerves (yellow fibers) are also arranged in a lower and an upper plexus at the junction of the dermis and subcutaneous fat and in the upper dermis. Sweat glands and hair follicles with their associated sebaceous glands are also integral components of skin. (From Adkinson NF, Yunginger JW, Busse WW, et al, editors. Middleton’s allergy: principles and practice. 6th ed. St. Louis: Mosby; 2003.)

One issue that is often of concern is the depth of burns. Determining between deep partial-thickness and superficial partial-thickness burns is difficult because it may take time for a definitive area of demarcation to develop. The usual method of distinction, blistering (which occurs with deep partial-thickness burns, or second-degree burns), can be delayed; however, it is the only distinction that is available early. Third-degree burns are insensate.

With all burn patients, assessment of the airway is critical. Signs of deep injury are stridor, soot in the mouth, and singed nasal hairs; any of these signs should indicate the need for close monitoring and more aggressive airway management. Swelling can occur rapidly in burned tissues, so signs of airway involvement should suggest earlier intubation because decompensation may occur rapidly.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

In each patient with a burn, the airway is still the most important component. Burn victims are often also subject to smoke inhalation or thermal injury to respiratory tissue from superheated air, and these injuries take priority over any others. Carbon monoxide, cyanide, and other inhaled toxins should be considered. The most threatening injuries are deep burns,
First degree
Superficial second degree

**Fig. 189.2** Depth of burns. First-degree burns are confined to the epidermis. Second-degree burns extend into the dermis (dermal burns). Third-degree burns are full-thickness burns through the epidermis and dermis. Fourth-degree burns involve injury to underlying tissue structures such as muscle, tendon, and bone. (From Townsend CM, Beauchamp RD, Evers BM, et al, editors. Sabiston textbook of surgery. 17th ed. Philadelphia: Saunders; 2004.)

**BOX 189.1 Criteria of the American Burn Association for Referral to a Burn Unit**

Partial-thickness burns involving greater than 10% total body surface area
Burns that involve the hands, face, feet, genitalia, perineum, or major joints
Third-degree (full-thickness) burns in any age group
Electrical burns, including lightning injury
Chemical burns
Inhalation injury
Burn injury in patients with preexisting medical disorders that could complicate management or recovery or could affect mortality
Patients with concomitant burn injury and trauma in which the burn injury poses the greatest risk for morbidity or mortality
Burned children in hospitals without qualified personnel or equipment for the care of children
Burn injury in patients who require special social, emotional, or long-term rehabilitative intervention

Children’s body surface area is significantly different from that of adults. A child’s head and torso account for a much larger percentage of body surface area than in an adult. Patients with serious burns need specific burn unit care and require transfer if such care is unavailable at the institution.

In patients with severe burn injuries, burn shock can occur. Hypovolemic shock develops from alterations in capillary permeability. Cell death can result in severe hyperkalemia, although this condition is usually a delayed finding.

**TREATMENT**

The first intervention for burn victims is assessment of the airway. Smoke inhalation is a common issue, so all patients who do not need immediate intubation should be given 100% humidified oxygen via a nonrebreather mask. Because edema can progress in minutes to hours and the full extent of respiratory damage may not become evident until 12 hours after the initial injury, patients with evidence of airway damage should be intubated prophylactically, before the airway becomes edematous (see the “Priority Actions” box).

Because of the expected hypovolemic state of these patients, two large-bore intravenous lines should be placed. Although placement of intravenous lines through burned skin is not optimal given that they allow another portal for infection into an open wound, it is preferable to having no intravenous access at all.

Fluid requirements are a key facet in the management of a burn patient. Two specific formulas are most commonly used. The Parkland formula is used to estimate fluid replacement in adults. This formula gives suggested fluid replacement in addition to maintenance fluid amounts over a 24-hour period; half of this fluid should be given over the first 8 hours, with the remaining half administered over the following 16 hours. The original Parkland formula used lactated Ringer solution as the fluid of choice.

For children, the Galveston formula is recommended for calculation of fluid repletion. The Galveston formula suggests that lactated Ringer solution with 5% dextrose should be used as the fluid of choice because of the lack of glycogen stores in the pediatric population. Again, half of the total amount should be given in the first 8 hours, with the remainder administered within the next 16 hours. Maintenance fluid should be
Fig. 189.3  A, The Lund and Browder charts are somewhat more accurate than the rule of nines in estimating the total body surface area burned. B, The proportion of total body surface area of individual areas, according to age. When compared with adults, children have larger heads and smaller legs. Other areas are relatively equivalent throughout life. The rule of nines is not accurate in determining the percentage of total body surface area burned in children. Ant, Anterior; L, left or lower; Post, posterior; R, right; U, upper. (From Roberts JR, Hedges J, editors. Clinical procedures in emergency medicine. 4th ed. Philadelphia: Saunders; 2004.)
also added, and particular attention should be paid to maintaining body temperature (see the “Facts and Formulas” box).

Despite these formulas, fluid resuscitation is more accurately based on appropriate urine output, which is 0.5 mL/kg/hr in adults and up to 1 mL/kg/hr in children. When one is uncertain about the patient’s fluid status, as may occur with congestive heart failure or pulmonary edema, a Swan-Ganz catheter may be necessary to provide guidance. Some controversy exists about the optimal fluid to use in burn patients. Although current guidelines specify crystalloid only initially, more recent studies suggest a probable role for colloid solutions.3,4

All burns should be gently cleansed of debris with normal saline solution. Superficial burns (superficial second- and first-degree burns) should be dressed with topical antimicrobial dressings, with frequent dressing changes planned (every 6 hours). A degree of controversy exists about the best antimicrobial dressing. No clearly superior agent has been reported in the literature.5 One commonly used agent, silver sulfadiazine, should not be applied to the face because of concerns about staining. A good option, particularly for the face, is a simple, over-the-counter antibiotic ointment. For mild burns, aloe vera cream is also acceptable. Biosynthetic dressings are another option, but because of cost and availability, these dressings are usually limited to inpatient burn management. A recent study showed a combination of hyaluronic acid plus silver sulfadiazine to be superior to just silver sulfadiazine alone.5

Deeper burns may require débridement and grafting. Specific recommendations should be discussed with the local burn center. If burns are in areas that can be elevated, they should be; this approach decreases the amount of subsequent edema that develops in the burn areas. Controversy also exists about whether burn blisters should be steriley incised or left alone. No definitive data on the subject are available, but the general consensus appears to be that unless a blister prevents the application of a dressing, it should be left intact.

Pain management is beneficial to the patient and is important to address early. Third-degree (full-thickness) burns are insensate, but more superficial burns are exquisitely painful. Most burns vary in depth and are painful, so early intravenous administration of morphine or hydromorphone (Dilaudid) is indicated for patients with extensive or deep burns. First-degree burns can be managed with oral nonsteroidal anti-inflammatory medications as a first-line therapy, although narcotics may be required. Superficial partial-thickness burns require oral narcotics for pain control.

Occasionally, a burn covers such a large area that it poses a risk for respiratory or vascular compromise. For example, a circumferential burn on an extremity can compromise the vascular supply to that extremity, whereas a nearly circumferential full-thickness burn on the chest can prevent chest movement and result in an inability to ventilate. Through escharotomies these constricting bands of tissue can be released (Table 189.2). The basic method of performing an escharotomy is to incise the constricting band of tissue down to subcutaneous fat. Fasciotomies for compartment syndrome may also be required with thermal burns that cause edema and subsequent increased compartmental pressure.

Much discussion has centered around empiric antibiotic administration. No data support the empiric use of antibiotics for acute burn wounds, except in topical form, as recommended for superficial burn wounds.6

Application of cold inhibits the production of lactate, release of histamine and thromboxane, and sequelae such as edema, microvascular congestion, and progressive ischemia. Cold should be used for small burns but not for large burns because hypothermia could result. Ice should not be applied directly because frostbite can increase tissue injury. Cold water can help relieve the pain of first- and second-degree burns, but patients with significant burns involving more than 9% of their total body surface area should not have cold applied.

### TIPS AND TRICKS

**Escharotomy**

- Consider local anesthesia (lidocaine).
- Pack the wound with gauze impregnated with topical antibiotic.
- Treat the escharotomy wound as part of the burn.

**Anesthesia**

- Large doses of intravenous narcotics may be necessary.
- Intubated patients still have pain—address it.

**Dressings**

- First, ensure adequate anesthesia.
- Gently clean the wound with normal saline solution.
- Assess the depth of each wound individually.
- For superficial wounds, dress with a topical antibiotic and cover with gauze.
- For deep wounds, consider burn unit referral, surgical débridement, or application of a dry dressing.

**Documentation**

**History**
Circumstances of the burn, timing, type of material burning, presence of associated trauma, presence of other victims, presence of voice change, presence of pain or paresthesias, weakness, tetanus status, medical conditions that may impair healing or compromise immune function, family situation

**Physical Examination**
Respiratory examination including signs of airway injury (soot in mouth, singed nasal hairs), neurovascular examination of all extremities, skin examination including wound size and depth, tenderness, neurologic examination, signs of concomitant trauma

**Studies**
None necessary unless associated with trauma; consideration of a chest radiograph for assessing pulmonary baseline status

**Medical Decision Making**
Reasons for intubation, reasons for transfer, initial cause of the thermal injury, follow-up plan

**Procedures**
Documentation regarding the need for escharotomy; if necessary, documentation of reversal of signs for escharotomy after the procedure

**Patient Instructions**
Documentation of discussion with the patient regarding the possibility of worsening injury and the warning signs of infection and vascular compromise; instructions on what to do and when to return

**Patient Teaching Tips**
Inform all burn patients about the remote possibility that the burn may worsen over the next 24 hours, with tissue death possibly requiring grafts.
After the first couple of days, a normal wound should exhibit consistently gradual improvement in pain, swelling, size, and tissue color.
Inform patients that a burn may result in a scar and probably will; the size and shape of the scar can be addressed by a plastic surgeon, who may need to perform a scar revision to obtain the desired cosmetic result.
If any of the foregoing situations develop, the patient should know to return to the emergency department or to follow up with specialty referral.
Assure patients that if they follow these instructions, additional steps can then be taken to optimize recovery.
Care of a partial-thickness burn: Check the burn every day for signs of infection, such as increased pain, redness, swelling, or pus. If you see any of these signs, go to your doctor right away. To prevent infection, avoid breaking blisters. Change the dressing every day. First, wash your hands with soap and water. Then gently wash the burn and put antibiotic ointment on it. If the burn area is small, a dressing may not be needed during the day.
Burned skin itches as it heals. Keep your fingernails cut short and do not scratch the burned skin. The burned area will be sensitive to sunlight for up to 1 year. Sunscreen has been shown to decrease how severe scars appear and should be used regularly.
FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

Patients with major burns should receive care in a specialized burn center (see Box 189.1). Minor burns can be cared for on an outpatient basis with close follow-up and instructions for assessing for infection. Patients should be informed of what to expect over the days and weeks following their burn (see the “Patient Teaching Tips” box). All patients with concern for possible nonaccidental burns should be evaluated by both social services and law enforcement, and patients with self-inflicted injuries should be referred for psychiatric care. Any pediatric patient suspected of suffering abuse should be admitted to the hospital, even if the burn itself does not meet admission criteria, so that social services can ensure the child’s safety (see the “Red Flags” box).

Chemical Burns

Jeffrey Druck

KEY POINTS

• Copious, immediate irrigation is the most important treatment of chemical burns.
• Elemental metal burns are the only chemical burns that should not be irrigated with water. Instead, wipe the material off with dry gauze and protect yourself from contamination.
• Identifying the cause of a chemical burn may be difficult, but the use of external resources (material safety data sheet, paramedics, employers, poison center) will help characterize the agents.
• Patients who exhibit no further signs of systemic toxicity may require only a chemistry panel and an electrocardiogram to complete an assessment.
• Patients with hydrofluoric acid burns require topical treatment with calcium gluconate, local infiltration of calcium gluconate, or for the most severe cases, intraarterial administration of calcium gluconate.

EPIDEMIOLOGY

Chemical burns are an unusual type of burn because the tissue injury is caused by the chemical reaction rather than by thermal damage. Chemical burns are common at work, at home, or in association with hobbies. One study found 22% of all pediatric burns to be a result of chemical burns, whereas other studies have estimated the percentage of admitted burned patients with chemical burns to be between 10% and 14%. With the recent concerns over terrorism, chemical agents have been emphasized as a possible method of attack, so knowledge of chemical burns is critical in the education of today’s emergency physicians. In addition, failure to recognize chemical burns or to treat them appropriately can have a detrimental impact not only on patients but also on care providers.

PATHOPHYSIOLOGY

Different chemical burns affect tissue by different mechanisms. Table 190.1 provides different categories of chemical agents and their mechanism of tissue damage. Most chemical burns involve skin; accordingly, knowledge of skin anatomy is key to understanding the pathophysiology of various chemical burns because of the link to treatment. A direct injury results when the epidermis is penetrated. Systemic absorption is possible once the injury extends through the dermis.

PRESENTING SIGNS AND SYMPTOMS

A classic example of a chemical burn is an industrial worker who “got something” on his or her arm and pain and sloughing of the skin developed over the next few minutes. The burning may have continued despite irrigation. An alternative example may be someone who got something on his or her clothes and noticed burning and a “rash” after touching the clothing.

In our modern times, chemical agents may be used in a terrorist attack, so multiple victims with similar burns and systemic toxicity should trigger concern for a mass casualty event. In addition, burns that appear to worsen over short periods may not be thermal burns, as initially thought, but instead may be chemical.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

With chemical agents, the initial complaint may be a red, burning rash; because some agents cause a delayed onset of symptoms, chemical burns should be considered in the differential diagnosis of all rashes. However, there is usually a direct cause-and-effect relationship that makes the diagnosis easy. Treatment, however, varies with the agent, identification of which may be more difficult. The most important task is to identify the offending agent. Various resources can be used, but the best source of information is usually patients themselves. The job site may provide clues, but the employer should also have the material safety data sheet available. Paramedics or others can bring in bottles of the agent, which may have a list of ingredients. The presence of systemic symptoms may also suggest specific agents.

Although the specific agent may be difficult to identify without other information, further testing can assist in the diagnosis. pH paper can be used on the wound to determine the presence of acid or base. A chemistry panel may suggest
acidity, whereas hypocalcemia may suggest exposure to hydrofluoric acid.

The gowns and gloves readily available in the hospital are not sufficient for many substances. Most chemicals penetrate these materials immediately. Relatively inexpensive, chemical-resistant, multilayer suits are available. Furthermore, respiratory precautions may be indicated for some agents. For these reasons, both hospital and community resources may be required for safe and expedient decontamination.

HAZARDOUS MATERIALS

The U.S. Department of Transportation requires color-coded identification of the type of material transported. These identifying codes are widely used. Additionally, a standard four-number code should be present to identify or characterize the agent more specifically. Figure 190.1 indicates the general categories and identifying colors, which include the following:

- Explosives (solid orange)
- Nonflammable gases (solid green)
- Flammable liquids (solid red)
- Oxidizers and peroxides (solid white and red stripes)
- Poisonous and biohazards (solid yellow)
- Radioactive materials (half white, half yellow, with a black radiation symbol)

**TREATMENT**

The first step in caring for patients with chemical burns is removal of the offending agent. This involves copious irrigation with several liters of either water or normal saline solution. All contaminated clothing should be removed, with care taken to ensure that health care providers are not exposed.

**ELEMENTAL METALS: DO NOT IRRIGATE**

Regardless of the type of offending agent, copious irrigation is the first step, with one exception: elemental metals. Elemental sodium and potassium cause exothermic reactions when exposed to water, in addition to forming toxic alkali agents. Patients with these injuries should undergo specific decontamination and removal of the offending metal by brushing it off with gauze. The poison center may provide advice about proper disposal of the metal.

Figure 190.2 is an algorithm for the management of patients with possible chemical burns.

**OCULAR EXPOSURE**

Ocular chemical burns are highly morbid injuries. The initial therapy of copious irrigation cannot be emphasized enough. Lid retraction with eversion is a key procedure to remove all chemical particles. Testing for the continued presence of chemicals can be accomplished with pH paper, but it is important to wait a minimum of 5 minutes after irrigation to make sure that the pH of the irrigation fluid is not being checked. Patients with burns caused by certain chemicals may require admission for continuous irrigation. Any patient with ocular exposure that results in corneal burns (identified by fluorescein examination) should have an ophthalmology consultation. Other elements of the examination are similar to any eye examination and include visual acuity, slit-lamp examination, and visual field evaluation. Tap water is recommended as the initial irrigating agent (because it is the most easily obtained and time until irrigation is a key element), but normal saline, lactated Ringer solution, and buffered solutions all work effectively.

**INGESTIONS**

Although discussion of the management of caustic chemical ingestion is beyond the scope of this chapter, two key concepts should be emphasized. First, the primary issue is maintenance of the airway. Second, the extent of burn is usually limited to the initial exposure, and decontamination of the gastrointestinal tract is difficult and not recommended; the only substance that has been suggested is water, but because of possible exothermic reactions resulting from attempted water
irrigation, water decontamination of the gastrointestinal tract is controversial. Endoscopy is the only method for definitive assessment of the degree of injury, but the common complications of perforation and mediastinitis should also be assessed. Some recent studies suggest that not every patient with a chemical burn involving the esophagus requires endoscopy, but consultation with gastroenterology and toxicology is recommended.

**INHALATIONAL INJURY**

Again, the primary issue in patients with inhalational injury is maintenance of the airway. For a variety of chemicals, the initial chest radiograph and the absence of respiratory symptoms belie the serious pulmonary edema or tracheobronchitis that may develop even days later. Consultation with the local poison control center while supportive measures are being instituted is the recommended pathway of care.

**DIRECTED THERAPIES**

Specific agents are known to cause specific toxicities. If the substance is known, therapy should be directed against that toxicity (Table 190.2).

**Hydrofluoric Acid**

Hydrofluoric acid is used in glass etching, automotive and industrial wheel cleaning, brick cleaning, semiconductor manufacturing, metal purification, and other industries. Immediate irrigation is indicated, as with other chemical injuries, but hydrofluoric acid can cause progressive tissue damage. Extensive exposure of an uncovered arm or leg can
be fatal. Pain may be delayed but can subsequently continue for hours or days. The hydrofluoric acid ion does not dissociate but rather penetrates tissues deeply and reacts with calcium and magnesium. Hypocalcemia can result.

Patients with mild, limited superficial exposure can be treated with topical calcium gluconate, which must usually be mixed in the emergency department by combining calcium gluconate powder with commonly available lubricant jelly. Affected fingers and hands can be placed in a medical glove that contains the solution. \textsuperscript{7}

Subcutaneous infiltration of 10\% calcium gluconate may help relieve the pain, but it also irritates the tissue. Slow infiltration with the smallest available needle, preferably 30 gauge, or dilution of the solution may minimize tissue damage. Intraarterial administration of 10\ mL of calcium gluconate mixed in 50\ mL of 5\% dextrose in water through the radial or ulnar artery via an arterial line over a 4-hour period may be beneficial for severe exposures to the hand.

Cardiac dysrhythmias may result from systemic hypocalcemia and hypomagnesemia. The electrocardiogram should be monitored for QT prolongation. Calcium and magnesium should be administered as needed.

### FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION

After determination of the offending agent and copious irrigation until no further chemical remains (for acids and bases, this can be determined with pH paper), disposition of the patient should be based on the presence of systemic symptoms, the size and depth of the burn, the nature of the agent, and access to appropriate follow-up. All patients should be warned about scarring and the potential for infection. The circumstances of the exposure should be verified, and appropriate state and local authorities should be notified about exposures in industrial incidents.

KEY POINTS

- Rashes are a common reason for a visit to the emergency department. Some rashes are simple and straightforward. However, others represent the initial complaint of a patient with a life-threatening disease.
- Fever with a rash is key to recognizing some of the more dangerous conditions.
- The key for differentiating a diffusely erythematous rash includes the presence or absence of the Nikolsky sign.
- Key factors for differentiating a maculopapular rash include its distribution and target lesions.
- A vesiculobullous rash is also differentiated by distribution; a localized or diffuse distribution helps narrow the differential diagnosis.
- Petechial/purpuric rashes are differentiated by the presence or absence of palpable lesions.
- Petechiae do not blanch with pressure.
- Palpable purpura occurs in vasculitic diseases secondary to inflammation or infection.
- Nonpalpable purpura is characteristic of thrombocytopenic conditions.
- Bullous rash with mucosal involvement is worrisome, and steroid therapy may be warranted.
- A careful history and physical examination are crucial for narrowing the differential diagnosis of an unknown rash.

EPIDEMIOLOGY

Evaluation of rashes ranks highly among the top 20 reasons for visits to the emergency department.

A well-reasoned algorithmic approach to the evaluation of rashes might aid the emergency medicine specialist in identifying the most common and potentially lethal rash syndromes. Although an exhaustive review of all potential fungal, parasitic, and viral causes of rash is beyond the scope of this chapter, the algorithms presented will equip physicians to quickly recognize the most common and critical rashes. Pediatric rashes are discussed in detail in Chapter 18. Additionally, the most life-threatening rashes are discussed in more detail in Chapter 192.

PATHOPHYSIOLOGY

A rash is a skin eruption that has a defined morphology and location. The morphology of the rash is usually distinct and related to the pathophysiologic dysfunction of the skin. Most severe rashes begin as exanthems (from the Greek exanthema, which means “breaking out,” and anthos, which means “flowering”). These rashes subsequently take on a particular morphology, characteristic lesions, or distribution. Table 191.1 delineates the most common terms used for skin lesions. Understanding these terms helps one better document progression of disease and facilitates communication with consulting physicians.

PRESENTING SIGNS AND SYMPTOMS

Eliciting the initial distribution and progression of a rash is essential. Additionally, the involvement of palms, soles, and mucous membrane is of key importance. It should be kept in mind that dysphasia, as well as eye or genital irritation, may be a manifestation of mucosal involvement and is often the initial symptom of several life-threatening conditions. The rash’s rapidity of progression is also an essential in diagnosis. Box 191.1 categorizes these important findings.

PHYSICAL EXAMINATION TIPS

Evaluation of vital signs is essential. Fever and hypotension, in particular, are ominous findings that mandate expedited and intensive care. Additional findings of concern on physical examination include a new-onset heart murmur or nuchal rigidity. Generalized lymphadenopathy is present with many illnesses, including mononucleosis, human immunodeficiency virus (HIV) infection, other infections, serum sickness, and drug reactions.

To ensure that lesions on the back, buttocks, and perineum are identified, patients should be completely undressed. Patients are often unaware of lesions present in these locations. Shoes and socks should also be removed, especially in diabetic patients. Toenails should be inspected closely for signs of systemic disease or fungal infection. Some fungal foot infections can cause an id (autoeczematization) reaction and exacerbate eczema in the upper extremities. Treatment of the fungal infection will be necessary to control the dermatitis. Additionally, the fingers, toes, palms, and soles should be examined closely for the distribution of the rash and stigmata of endocarditis.
CHAPTER 191  ■  APPROACH TO THE ADULT RASH

SPECIFIC SIGNS
Two signs are important in the evaluation of these rashes: the Nikolsky sign and the Asboe-Hansen sign. A positive Nikolsky sign (Fig. 191.1) is noted when slight rubbing of the skin results in exfoliation of the outermost layer with lateral extension of the erosion into the intact skin. The area of denuded skin is pink and tender. The Asboe-Hansen sign (indirect Nikolsky sign or Nikolsky II sign) is extension of a blister into normal skin with the application of light pressure on the top of the blister. All patients with tender, blistering, or sloughing skin should be evaluated serially for these important signs.

DIFFERENTIAL DIAGNOSES AND MEDICAL DECISION MAKING
History taking is an essential component in formulating appropriate differential diagnoses and guiding medical decision making. Inquiry regarding the patient’s travel, medical, occupational, recreational, and medicinal history is required. Once the history and physical examination are complete, in-depth evaluation of the rash is in order. The differential diagnoses can be narrowed by categorizing the rash as erythematous, maculopapular, petechial/purpuric, or vesiculobullous.

TRAVEL HISTORY
Lyme disease is common in the mid-Atlantic, central, western, and northeastern parts of the United States. Patients who have recently traveled to the Caribbean may have dengue fever. In addition, patients reporting recent camping and travel through

BOX 191.1 Distribution and Progression of a Rash

Distribution and Spread
- Begin peripherally, then spread centrally
  - Rocky Mountain spotted fever
  - Erythema multiforme
  - Vasculitides
- Begin centrally, then spread peripherally
  - Viral exanthems
  - Smallpox

Involvement of Palms and Soles
- Diffuse involvement (more serious and lethal)
  - Rocky Mountain spotted fever
  - Erythema multiforme
  - Stevens-Johnson syndrome
  - Toxic epidermal necrolysis
  - Syphilis
  - Bacteremic endocarditis
- Localized involvement
  - Contact dermatitis
  - Infectious process

Involvement of Mucous Membranes
- Toxic epidermal necrolysis
- Stevens-Johnson syndrome
- Pemphigus vulgaris
- Kawasaki disease
- Viral syndromes

Rapidity of Rash Progression
- Spread in minutes
  - Urticarial anaphylaxis
- Spread in hours
  - Meningococcemia
- Spread in days
  - Drug reactions

Fig. 191.1  Fragile blisters rupture easily to form painful erosions. Finger pressure separates normal-appearing epidermis and produces an erosion (Nikolsky sign). Pressure on the edge of a blister spreads the blister into unaffected skin (Asboe-Hansen sign). (From Habif TP, editor. Clinical dermatology, 5th ed. Philadelphia: Mosby; 2009. Figure 16-14.)
**Algorithm for erythematous rashes.**

**Febrile**
- Staph SSS (child)
- TEN (adult)

**Afebrile**
- Toxic shock syndrome (TSS) (mucous membranes)
- Kawasaki syndrome (children)
- Scarlet fever (sandpaper)

If a Nikolsky sign is present, the differential diagnosis includes Kawasaki syndrome (children) and toxic shock syndrome (TSS). If fever is present without a Nikolsky sign, the differential diagnosis includes Kawasaki syndrome (children), staphylococcal scalded skin syndrome (SSSS), and toxic shock syndrome (TSS). If fever is present without a Nikolsky sign and to staphylococcal scalded skin syndrome (SSSS), generally in infants and young children. If fever is present without a Nikolsky sign, the differential diagnosis includes Kawasaki disease, scarlet fever, erythroderma, and toxic shock syndrome (TSS). Patients with an erythematous rash but without a fever or Nikolsky sign may be having an anaphylactic reaction or a reaction to vancomycin, scombroid, or alcohol exposure. Please refer to Chapter 192 for review of TEN, TSS, and erythroderma.

**Maculopapular Rashes**
The term *maculopapule* is a portmanteau of macule and papule. Maculopapular rashes are differentiated by the distribution of the rash and systemic toxicity (Fig. 191.3). Patients with centrally distributed rashes who appear toxic and febrile have a wider differential diagnosis; however, it is paramount that patients living in endemic areas be assessed for Lyme disease. Those with centrally distributed rashes but no signs of toxicity usually have either a drug reaction or pityriasis rosea. Patients with peripherally distributed rashes have a broader differential diagnosis that is dependent on systemic toxicity, the presence or absence of target lesions, and whether the rash is located on the flexor or extensor surfaces. Target lesions (Fig. 191.4) are pathognomonic for SJS or erythema multiforme (EM). The target lesion of Lyme disease is usually a single large bull’s eye that measures at least 5 cm in diameter (erythema migrans). Patients with peripheral lesions and systemic toxicity but without target lesions require emergency evaluation for meningococcemia, RMSF, and syphilis. Non-toxic patients with a peripherally distributed rash and no target lesions require further assessment for flexor involvement (scabies or eczema) or extensor involvement (psoriasis). Please refer to Table 191.2 for review of EM minor and major. See Chapter 18 for review of viral exanthems. Please refer to Chapter 192 for review of Lyme disease, meningococcemia, RMSF, SJS, and syphilis.

**Petechial/Purpuric Rashes**
These rashes can be especially challenging and are associated with devastating differential diagnoses; however, an algorithmic approach can help the physician narrow the diagnosis with confidence (Fig. 191.5). By definition, petechiae do not blanche with pressure; additionally, remembering the cause of palpable versus nonpalpable lesions is paramount. Palpable (raised) purpura occurs in vasculitic diseases secondary to inflammation or infection. Nonpalpable purpura (flat, subcutaneous hemorrhages) are seen with thrombocytopenic conditions. Patients with petechial/purpuric rashes and fever or toxicity require emergency evaluation. If the lesions are
Vesiculobullous Rashes
Vesiculobullous rashes provoke significant angst in many physicians (Fig. 191.6). However, the differential diagnosis can be greatly simplified by categorizing patients with these rashes as febrile or afebrile and noting whether the distribution of the rash is diffuse or localized. Patients with a diffuse vesiculobullous rash and a fever may have varicella or a more devastating illness such as smallpox, disseminated gonococcal disease, or purpura fulminans/DIC. Necrotizing fasciitis and hand-foot-and-mouth disease are characterized by localized lesions and fever. In afebrile patients with a diffuse vesiculobullous rash, the differential diagnosis includes bullous pemphigus (BP) and pemphigus vulgaris (PV). One of the distinguishing features is based on the Nikolsky sign. A positive Nikolsky sign is seen with PV but is absent in BP. These

|                            | Rash appears in 1-2 wk  |
| Rash characteristics       | Symmetric extremity lesions that develop into target lesions  |
|                            | Begins as a maculopapular rash that evolves into target lesions; rapidly progressive with centripetal spread |
| Distribution               | Lower extremities  |
|                            | Palms, soles, dorsa of hands, face, and extensor surfaces |
| Mucous membrane involvement| None  |
|                            | Significant mucous membrane involvement  |
|                            | Eye involvement (10%); often bilateral, purulent conjunctivitis |
| Pruritic                   | Yes  |
|                            | No |
| Diagnosis                  | Confirmed with biopsy  |
|                            | Confirmed with biopsy |
| Treatment                  | Usually outpatient management  |
|                            | Treatment of the cause  |
|                            | Symptomatic support  |
| Cold compresses            | Discontinue use of the offending agent  |
| Analgesics                 | Fluid and electrolyte balance  |
| Topical steroids           | Analgesics  |
| Treatment of the cause     | Wound care (avoid silver sulfadiazine)  |
| Discontinue use of the     | Soothing oral solutions  |
| offending agent            | Dermatology consultation  |
| Dermatology follow-up      | Ophthalmologic consultation  |
|                            | Intravenous steroids may increase complications |

Physical examination pearl: In contrast to Stevens-Johnson syndrome or toxic epidermal necrolysis, the target lesions of erythema multiforme are discrete rather than confluent, and the skin is not usually tender. The skin is very tender with toxic epidermal necrolysis.

Fig. 191.6  Algorithm for vesiculobullous rashes. DIC, Disseminated intravascular coagulopathy; GC, gonococcal disease. (From Murphy-Lavoie H, LeGros TL. Emergent diagnosis of the unknown rash: an algorithmic approach. Emerg Med 2010;42[3]:6-17.)
entities are regularly confused, and it is essential to differentiate them urgently. It is important to remember that both BP and PV have strong associations and known triggers. For those with BP, the list of drug triggers includes furosemide, ibuprofen, captopril (or other thiol-containing compounds), penicillin, and antibiotics. Patients with PV have similar drug triggers (with the addition of rifampin). Please refer to Table 191.4 for additional associations for PV and BP. The differential diagnosis is simpler and less of an emergency in a patient who is afebrile with a localized vesiculobullous rash; contact dermatitis, herpes zoster, dyshidrotic eczema, and burns are included in the differential diagnosis. Please refer to Table 191.4 for a discussion of PV and BP. Refer to Chapters 18 and 192 for review of varicella and Chapter 192 for review of smallpox, purpura fulminans/DIC, and necrotizing fasciitis.

### TREATMENT

The type of rash, the overall health and physical reserves of the patient, and the rapidity of diagnosis determine treatment. Many of these diseases are associated with significant morbidity and mortality, and a high index of suspicion is required to prevent a delay in diagnosis.

## ERYTHEMATOUS RASHES

### Febrile Patients with a Positive Nikolsky Sign

These patients are systemically ill and require intensive treatment. Patients with SSSS usually require hospitalization for fluid and electrolyte management and supportive wound and skin care. Young, well-appearing patients with SSSS and minimal skin sloughing may be managed as outpatients. However, adult patients with SSSS have a 60% mortality rate and require much closer monitoring. Antibiotics are usually recommended, but is it unclear whether they measurably alter the course of the disease. Please refer to Chapters 18 and 192 for further review. Patients with TEN require immediate discontinuation of the offending agent, wound care, eye care, fluid and electrolyte resuscitation, and admission to either an intensive care unit (ICU) or burn unit. Intravenous immune globulin (IVIG) may be helpful, but it has yet to be approved by the Food and Drug Administration for this use. Most

1604
Afebrile Patients Without a Nikolsky Sign

These patients have exposure reactions. Anaphylaxis is a medical emergency that calls for immediate intervention. These patients require intravenous access, cardiac monitoring, high-flow oxygen, fluid resuscitation, airway management as indicated (laryngeal edema), inhaled \( \beta \)-agonists (wheezing or stridor), corticosteroids or aminophylline (for refractory bronchospasm), and epinephrine. The use of epinephrine is not contraindicated in this emergency. However, there is a death correlation associated with delay in administration. Scombroid toxicity is treated with antihistamines and supportive care. Complications are rare, and usually no further treatment is needed. Patients who experience an alcohol flush reaction require supportive care and should limit their alcohol consumption because their symptoms are due to an accumulation of acetaldehyde, a known carcinogen. Vancomycin red man syndrome is a drug-induced infusion reaction characterized by flushing and an erythematous rash secondary to mast cell degranulation. Hypotension and angioedema may occur and require close monitoring. Treatment consists of antihistamines. An extreme vancomycin-induced drug reaction results in an overwhelming exfoliative dermatitis that requires hospital admission, fluid and electrolyte management, skin physicians recommend against steroid use. It is important to avoid sulfadiazine on these wounds because sulfa is a common offending agent.

Febrile Patients Without a Positive Nikolsky Sign

These patients are systemically ill and require intensive treatment. Patients with TSS require immediate removal of the infective material, intravenous antibiotics, fluid resuscitation, ICU admission, and consideration of the use of IVIG. Erythroderma is a devastating and overwhelming disease. All patients require admission, fluid and electrolyte monitoring, skin care, antihistamines, prevention of secondary infection, treatment of the underlying cause, and topical steroids. Systemic steroids are controversial. Recovery is long and recurrences are common. Patients with Kawasaki syndrome require high-dose aspirin immediately, hospitalization, and IVIG. Those with scarlet fever require penicillin to prevent local suppurtive complications and acute rheumatic fever. Please refer to Chapter 18 for review of scarlet fever. Refer to Chapter 192 for review of erythroderma. Refer to Chapters 18 and 192 for review of Kawasaki disease and TSS.

and wound care, topical steroids, and treatment of complications.

**MACULOPAPULAR RASHES**

**Central Maculopapular Rashes in Febrile or Ill-Appearing Patients**

These patients usually have viral exanthems. They are typically ill appearing with fever but are not moribund. Most patients respond to supportive care. Please refer to Chapter 18 for a discussion of pediatric exanthems.

**Central Maculopapular Rashes in Well-Appearing Patients**

These patients may be having a drug reaction. Many drugs have been implicated: antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), chemotherapeutic agents, anticonvulsants, and psychotropics, among others. Treatment includes discontinuation of the offending agent, and most care is supportive. Severe reactions, such as SJS, TEN, and hypersensitivity reactions, require hospital admission, meticulous wound care, and intensive support. Pityriasis is also in the differential diagnosis of well-appearing patients with central maculopapular rashes, and usually no treatment is required because it is generally a self-limited disease. For symptomatic pruritus, zinc oxide and calamine lotion are useful.

**Peripheral Maculopapular Rashes in Febrile or Ill-Appearing Patients with Target Lesions**

These patients may have EM major (refer to Table 191.2 for review). SJS and Lyme disease are also in the differential diagnosis. Treatment of SJS involves discontinuation of the offending agent, optimization of fluid and electrolyte balance, meticulous wound care, and ICU admission. For patients with Lyme disease, doxycycline is first-line treatment in nonpregnant adults. Children are treated with amoxicillin. Refer to Chapter 192 for further review of SJS and Lyme disease.

**Peripheral Maculopapular Rashes in Febrile or Ill-Appearing Patients Without Target Lesions**

These patients may have meningococcemia, RMSF, or syphilis. Patients with meningococcemia require intravenous ceftriaxone, with vancomycin added in cases of diagnostic uncertainty or to cover resistant streptococcal meningitis. Dexamethasone reduces neurologic sequelae if administered early and before antibiotics if possible. These patients also require admission and continuous surveillance for end-organ damage and complications. RMSF is always in the differential diagnosis in patients with these rashes or in those in whom meningococcemia is suspected. With any diagnostic uncertainty, one should treat for both illnesses. Doxycycline is the drug of choice in all nonpregnant patients with RMSF, even children. Pregnant patients may be treated with chloramphenicol, although doxycycline should also be considered because it is simply more effective. Secondary syphilis is also a diagnostic possibility in these patients and should be treated with intramuscular penicillin G in all patients. Benzathine penicillin should not be used because it does not penetrate cerebrospinal fluid. Pregnant patients allergic to penicillin should undergo desensitization. Nonpregnant, penicillin-allergic patients may be treated with doxycycline.

Refer to Chapter 192 for further information on meningococcemia, RMSF, and syphilis.

**Peripheral, Flexural, Maculopapular Rashes in Well-Appearing Patients**

These patients may have scabies or eczema. Scabies usually responds to household hygiene, a scabicide, and antihistamines. Eczema (Fig. 191.7) is treated with topical steroids, cold compresses, and ultraviolet light.

**Peripheral, Extensural, Maculopapular Rashes in Well-Appearing Patients**

These patients may have psoriasis and usually respond well to the use of moisturizers, salicylic acid, light therapy, sun exposure, topical steroids, oatmeal baths, stress reduction, and dermatologic follow-up.

**PETECHIAL/PURPURIC RASHES**

**Palpable Petechial/Purpuric Rashes in Febrile Patients**

These patients have wide differential diagnoses with high morbidity and mortality. Meningococcemia and RMSF were discussed in the section related to the treatment of maculopapular rashes. Treatment of disseminated gonococcemia is reviewed in Table 191.3. Patients with endocarditis require early recognition, intensive therapy, broad-spectrum antibiotics to cover methicillin-resistant *Staphylococcus* (with subsequent guidance by blood cultures), and cardiology consultation. See Chapter 192 for further information on endocarditis. HSP is a small vessel vasculitis that is usually self-limited, and treatment is supportive. NSAIDs are used to reduce joint and soft tissue pain. Patients with significant bleeding, intussusception, and renal failure require admission for HSP. Please refer to Chapter 192 for review of endocarditis and Chapter 18 for review of HSP.

**Nonpalpable Petechial/Purpuric Rashes in Febrile Patients**

Purpura fulminans and DIC are acutely life-threatening disorders that require emergency hematology consultation and ICU admission. First-line therapy is treatment of the underlying cause. Folate, vitamin K, fresh frozen plasma, cryoprecipitate, platelets, and red blood cell transfusions are given as needed. Heparin is also used for associated thrombi. These patients are very ill, and use of these therapies is best done in
consultation with the ICU team and a hematologist. TTP is a devastating disease with greater than 90% mortality if not treated properly. Treatment includes emergency hematology consultation, treatment of the underlying cause, fresh frozen plasma (as a temporizing measure), plasmapheresis, and ICU admission. It is important to avoid platelet administration because it will precipitate more thrombus formation. Exchange transfusions can reduce mortality to 10%, and facilities without these capabilities should consider early transfer. Please refer to Chapter 192 for further review of purpura fulminans/DIC and TTP.

**Petechial/Purpuric Rashes in Afebrile Patients**

These patients may have a vasculitis (palpable rash) or ITP (nonpalpable rash). Please refer to Table 191.3 and Box 191.2 for reviews of these petechial/purpuric rashes.

**VESICULOBULLOUS RASHES**

**Febrelic Patients with a Diffuse Rash**

These patients may have varicella, smallpox, disseminated gonococccemia, or purpura fulminans/DIC. Varicella is a childhood viral exanthem (chickenpox) that is intensely pruritic. Treatment is supportive and consists of wet dressings, soothing baths, calamine lotion, surveillance for secondary infection, and antihistamines. The role of acyclovir in healthy children is unclear. Immunocompromised patients are at risk for significant complications. Maternal infection in the first trimester may result in devastating congenital varicella syndrome, whereas perinatal maternal infection predisposes to disseminated neonatal herpes. Smallpox is a dreaded variola infection against which 50% of the U.S. population has not been vaccinated. Care is supportive, and all personnel with smallpox exposure require quarantine and vaccination. The mortality rate is 30% in those who are unvaccinated. Treatment of disseminated gonococccemia is reviewed in Table 191.3. Treatment of purpura fulminans/DIC was reviewed with petechial/purpuric rashes. Please refer to Chapter 18 for review of varicella and Chapter 192 for review of smallpox and purpura fulminans/DIC.

**Febrelic Patients with a Localized Rash**

Necrotizing fasciitis is in the differential diagnosis for these patients. It is an acutely toxic bacterial infection with very high mortality. Treatment consists of prompt surgical débridement, broad-spectrum antibiotics, and adjunctive hyperbaric oxygen therapy. Hand-foot-and-mouth disease is a highly contagious viral illness that requires symptomatic care for the painful oral ulcers. Complications are rare; however, infection during the first trimester of pregnancy may result in spontaneous abortion. Please refer to Chapter 192 for review of necrotizing fasciitis and Chapter 18 for review of hand-foot-and-mouth disease.

**Afebrile Patients with a Diffuse Rash**

These patients have either BP or PV. Both these diseases and their treatments are reviewed in Table 191.4.

**Afebrile Patients with a Localized Rash**

These patients may have herpes zoster, dyshidrotic eczema, or a local burn. Herpes zoster or shingles (caused by varicella virus) is a self-limited illness that will resolve without intervention. However, treatment is required for immunocompromised patients and those with ocular involvement or disseminated disease and is recommended for individuals older than 50 years, especially those with significant pain. High-risk patients require intravenous acyclovir, judicious administration of corticosteroids, ophthalmologic consultation (eye involvement), fluid and electrolyte monitoring, pain management, and supportive care. Treatment of dyshidrotic eczema was reviewed in the section on maculopapular rashes. Treatment of burns depends on the type, whether induced by trauma, chemicals, radiation, or heat. Treatment is also guided by the depth, severity, and surface area involved. Severe burn injuries are treated with intravenous fluid administration, early intubation (for airway involvement), removal or neutralization of the source of the injury, meticulous wound care, pain management, surgical intervention (early skin grafts or flaps, débridement, or escharotomy), and adjunctive hyperbaric oxygen therapy.

**FOLLOW-UP AND PATIENT EDUCATION**

**PATIENTS WITH ERYTHEMATOUS RASHES**

Follow-up is dependent on the cause of the rash, the patient’s baseline immunologic health, disease complications, treatment side effects, and patient resources. Toxic patients with an erythematous rash require admission, intensive treatment, and close follow-up because all these diseases are associated with either very high morbidity and mortality or the potential for devastating complications. Patients with TSS require education regarding infective bacterial material. Those with SSSS, erythroderma, TSS, and TEN require close surveillance for secondary infections and wound care therapy. Patients with Kawasaki syndrome and scarlet fever require pediatric or primary care follow-up for monitoring of complications. Patients with severe exposure reactions (anaphylaxis and vancomycin) require intensive treatment, critical care monitoring, and close follow-up for complications related to end-organ damage or the exfoliative dermatitis associated with vancomycin-induced erythroderma. Less serious exposure reactions (scombroid and alcohol flush) require primary care follow-up and patient education regarding exposure toxicities.

**PATIENTS WITH MACULOPAPULAR RASHES**

Patients with viral exanthems, drug reactions, and scabies have self-limited illnesses and benefit by close follow-up and patient education with their primary care provider regarding exposures and potential complications. Those with eczema, psoriasis, or pityriasis should be referred to a dermatologist for initial consultation and primary care follow-up. Patients with SJS or EM require close outpatient management for complications and wound care follow-up. Those with meningococccemia, RMSF, Lyme disease, or syphilis require primary care follow-up in conjunction with infectious disease consultation and monitoring.

**PATIENTS WITH PETECHIAL/PURPURIC RASHES**

Patients with meningococccemia, disseminated gonococccemia, RMSF, and endocarditis require close primary care
follow-up, as well as infectious disease consultation and monitoring. Additionally, follow-up of endocarditis should include cardiologist involvement. Patients with HSP should be monitored by their primary care physician for resolution of symptoms and for complications. Patients with purpura fulminans/DIC, ITP, and TTP must be monitored by a primary care provider, a hematologist, and a wound care specialist as needed. Those with vasculitis benefit from continued monitoring by their primary care provider, with dermatology consultation and wound care as appropriate.

**PATIENTS WITH VESICULOBULLOUS RASHES**

Patients with varicella, hand-foot-and-mouth disease, herpes zoster, dyshidrotic eczema, and contact dermatitis benefit from close primary care follow-up for pain control and monitoring for complications. Patients with smallpox, disseminated gonococcemia, and necrotizing fasciitis should follow up with their primary care physician, an infectious disease specialist, and a wound care specialist as needed. Patients with necrotizing fasciitis should also receive follow-up from their attending surgeon. Patients with purpura fulminans/DIC require close monitoring for continued improvement by a primary care physician and a hematologist. Wound care may be needed. Those with BP and PV benefit from close primary care follow-up, as well as dermatologic consultation and wound care.

**RED FLAGS**

- Fever and petechiae/purpura
- Mucous membrane involvement
- Hemorrhagic bullae
- Nikolsky sign
- Nonpalpable petechiae with neurologic symptoms

**SUGGESTED READINGS**

**REFERENCES**

References can be found on Expert Consult @ www.expertconsult.com.
REFERENCES

**PATHOPHYSIOLOGY**

The pathophysiology of rashes in severely ill patients is broad and depends on the cause. Most of these rashes result from devastating bacterial infections, viral infections, tick bites, drug reactions, vasculitides, or environmental triggers. Many of these diseases also have a high predisposition in those with comorbid conditions.

**PRESENTING SIGNS AND SYMPTOMS**

**HISTORY TAKING**

The history is of paramount importance in the diagnosis of a patient with a rash. Of particular concern is an accounting of any recent travel, the patient’s own geographic location, medical and occupational history, animal exposure, and medication regimens. Table 192.1 classifies rashes in severely ill patients by exposure to geographic regions and animals.

**PHYSICAL EXAMINATION**

At the start it is very important to evaluate the vital signs of toxic-appearing patients with rashes. Fever and hypotension are of particular concern and mandate expedited and intensive care. A complete examination should include evaluation for any new-onset heart murmur, changes in mental status, and nuchal rigidity. Of particular importance are the onset and progression of the rash; involvement of the palms, soles, and mucous membranes; and the age of the patient. An algorithmic approach can aid greatly in the identification of systemically ill patients with a rash. Table 192.2 categorizes rash characteristics in severely ill patients.

**PHYSICAL SIGNS**

Two signs are important in the evaluation of these rashes, the Nikolsky sign and the Asboe-Hansen sign. A positive Nikolsky sign (Fig. 191.1) is noted when slight rubbing of the skin results in exfoliation of the outermost layer with lateral extension of the erosion into intact skin. The area of denuded skin is pink and tender. The Asboe-Hansen sign (indirect Nikolsky sign or Nikolsky II sign) is extension of a blister into normal skin with the application of light pressure on top of the blister. All patients with tender, blistering, or sloughing skin should be evaluated serially for these important signs.

**INTRODUCTION**

Early in the disease process, life-threatening rashes may occur in relatively well-appearing patients. However, these patients may deteriorate rapidly, and early resuscitative measures, including pressure support with central venous access, aggressive respiratory care, and broad-spectrum antibiotic therapy, are crucial. Early recognition of these potentially lethal rashes is facilitated by morphologic classification and refined by serial physical examination.
**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

**ALGORITHMIC APPROACH TO CLASSIFICATION**

It is helpful to first define the rash into one of four types: erythematous, maculopapular, vesiculobullous, or petechial/purpuric (see Chapter 191 for more detailed review). Erythematous rashes can then be further classified into those with or without a positive Nikolsky sign. Maculopapular rashes may be subdivided into those with or without target lesions. Vesiculobullous rashes should be differentiated into those with a localized or a diffuse distribution. Petechial/purpuric rashes should be classified into those with palpable or non-palpable rash morphology (Table 192.3).

**ERYTHEMATOUS RASHES**

Erythematous rashes are characterized by diffuse redness of the skin as a result of capillary congestion.

Toxic patients with an erythematous rash may have specific signs that narrow the differential diagnosis. The combination of an erythematous rash in a toxic patient with a positive Nikolsky sign reduces the differential diagnosis substantially, usually to toxic epidermal necrolysis (TEN) in adults and staphylococcal scalded skin syndrome (SSSS).
in infants and young children. Alternatively, the differential diagnosis for toxic and febrile patients with an erythematous rash as well as a negative Nikolsky sign includes toxic shock syndrome (TSS), Kawasaki disease, and erythroderma (see Table 192.3). Table 192.4 details the symptoms, signs, mortality, and treatment of the aforementioned erythematous rashes. SSSS, TSS, and Kawasaki disease are also covered in Chapter 18.
**Toxic Epidermal Necrolysis**

TEN (Lyell disease) is the most serious cutaneous drug reaction. It is most commonly associated with sulfonamides; however, it has other important triggers as well. TEN is manifested as the sudden onset of diffuse erythema with tender skin and blistering. The skin cleavage is full thickness with positive Nikolsky and Asboe-Hansen signs and significant skin sloughing (Fig. 192.1). These patients are toxic and exhibit significant mucous membrane involvement. Symptoms occur first around the eyes, spread caudally (shoulders and upper extremities), and then progress to involve the entire body. Several populations are predisposed to TEN and others are at high risk (see Table 192.4). However, one group deserves expanded mention. It is important to consider that patients infected with human immunodeficiency virus (HIV) who are on a chronic regimen of trimethoprim-sulfamethoxazole prophylaxis and other polypharmacy have a 1000 times greater risk for TEN than do those without HIV.

**Staphylococcal Scalded Skin Syndrome**

Also known as Ritter disease or dermatitis exfoliativa neonatorum, SSSS is manifested as a scarlatiniform, erythematous rash caused by a staphylococcal infection that blisters and sloughs (positive Nikolsky sign). Children younger than 5 years are at highest risk.

**Toxic Shock Syndrome**

This toxin-mediated staphylococcal or streptococcal infection is historically associated with tampon use, although any staphylococcal or streptococcal source can precipitate TSS. Up to 45% of cases are unrelated to menses. Patients are overtly toxic, febrile, and in shock with a diffuse erythematous rash that eventually leads to desquamation of the hands and feet. The mortality associated with TSS is 30% to 70% and is usually due to multisystem organ failure and end-organ damage. Complications include azotemia, rhabdomyolysis, encephalopathy, thrombocytopenia, and liver dysfunction.

**Kawasaki Disease**

This childhood illness is also known as mucocutaneous lymph node syndrome or infantile polyarteritis. It is a vasculitis of unknown cause, although infective and autoimmune theories abound. It affects many organ systems, including the skin, mucous membranes, lymph nodes, and blood vessels. Diagnostic criteria include high fever for at least 5 days, diffuse erythroderma of the skin, strawberry tongue, significant cervical lymphadenopathy, conjunctival injection, peeling of the fingers and toes, and edema of the extremities. Thrombocytosis may also be present. By far the most serious complication is vasculitis of the coronary arteries, which leads to coronary vessel aneurysms, myocarditis, and myocardial infarction (even in the very young). Treatment consists of high-dose aspirin (given immediately), hospitalization with supportive care, and very importantly, intravenous immune globulin (IVIG) because Kawasaki disease does not respond to antibiotics.

**Erythroderma**

Erythroderma, also known as exfoliative dermatitis, is an erythematous, scaling rash that involves more than 90% of the skin. Erythroderma is also termed red man syndrome when a primary cause cannot be identified. The rash begins as a very generalized erythema. The skin begins to scale and slough, along with nails and hair. The skin is inflamed and may lose pigmentation in dark-skinned individuals. This is an overwhelming disease process in which large tissue burdens of exfoliated scales are lost en masse daily; these patients are, in essence, “burn victims.” They have marked increases in skin perfusion and profound temperature dysregulation that result in significant heat loss, increased basal metabolic rate, fluid loss, edema, and hypoalbuminemia. Although this disease primarily affects adults, it does occur in younger populations who have other skin or connective tissue disorders (lupus, sarcoid, psoriasis, SSSS, atopic dermatitis, or seborrheic dermatitis). Patients with rapid disease progression usually have a history of cancer or SSSS or an inciting medication reaction. Those with gradual symptomatology generally have a skin disorder history. The work-up for these patients should be conducted in close consultation with a dermatologist, who can aid in identification of the primary lesions, which can be a difficult task. All patients warrant cancer evaluation and treatment of the underlying cause. Laboratory studies include a sedimentation rate, complete blood count, comprehensive metabolic panel, HIV testing, skin scrapings, skin biopsies, and wound cultures. All patients warrant admission. In pediatric patients, erythroderma and fever are predictors of hypotension and may reflect TSS. Systemic steroids are controversial and may worsen psoriasis and SSSS. Recovery is long and recurrences common in the case of red man syndrome. Mortality ranges from 20% to 40% and in many instances is due to factors unrelated to the disease process itself.

**MACULOPAPULAR RASHES**

The term maculopapule is a portmanteau of macule and papule. Maculopapular rashes are differentiated according to the distribution of the rash and systemic toxicity (Table 192.5). Patients who appear toxic and febrile have a wide differential diagnosis; however, it is paramount that patients living in endemic areas be assessed for Lyme disease. Target lesions (see Fig. 191.4) are pathognomonic for Stevens-Johnson Syndrome (SJS) and erythema multiforme (EM). Refer to Chapter 191 for review of EM. A full discussion of...
TEN was presented in the previous section (erythematous rashes); however, TEN and Lyme disease may also be associated with target lesions. Toxic patients with a maculopapular rash but no target lesions require emergency evaluation for Rocky Mountain spotted fever (RMSF), syphilis, and meningococccemia (see Table 192.3).

**Stevens-Johnson Syndrome**

SJS is often a drug reaction, although infections and malignancies have been implicated. Previously, SJS was thought to be linked with EM, but it has recently been reclassified on the spectrum with TEN. These patients have diffusely distributed target lesions that include the palms and soles. Significant mucous membrane involvement is present as well (Fig. 192.2). Patients with SJS are toxic with many constitutional symptoms. Treatment involves discontinuation of the offending agent and optimization of fluid and electrolyte status. Steroid treatment is controversial. Both SJS and TEN have greater mortality (10% and 30%, respectively) than do EM major and minor (negligible morbidity and mortality). Patients with SJS require intensive care unit (ICU) admission.\(^2,5,8,14-16\)

**Lyme Disease**

This tick-borne illness is caused by *Borrelia burgdorferi*. The patient generally has erythema migrans (a large annular target lesion with a dark red border and central clearing) at the site of the tick bite (Fig. 192.3). The rash begins with tick inoculation and may therefore be central or peripheral in location.\(^9\) As the infection spreads hematogenously over a period of days to weeks, the patient may experience a variety of systemic symptoms, including a secondary rash (annular lesions), fever, meningitis, atrioventricular nodal block, migratory arthralgias, and myalgias. Neuritis occurs as well and is often manifested as Bell palsy (which may be bilateral); however, any nerve can be affected. The diagnosis is made clinically, although biopsy of the site of the tick bite is often diagnostic. Serologic tests are positive after several weeks but do not differentiate active from inactive infection. Though rarely lethal, Lyme disease can be accompanied by significant morbidity, usually related to neurologic and rheumatic complications. Doxycycline is first-line the treatment in nonpregnant adult patients. Children may be treated with amoxicillin. Ceftriaxone is indicated for those with significant neurologic or cardiac involvement.

SECTION XVIII  ■  CUTANEOUS DISORDERS

Rocky Mountain Spotted Fever
This tick-borne illness (*Rickettsia rickettsii*) has been recorded from Canada to Mexico and in every mainland state in the union except Vermont and Maine. Although history taking is essential, only 50% can recall a tick bite. The RMSF-associated erythematous, maculopapular rash begins on the wrists and ankles and spreads over the entire body (including the palms and soles). In its early stage the rash consists of reddish macules that blanch, only to become petechial and purpuric later. In up to 20% of patients, the rash is absent (spotless fever). Regardless of whether the rash is present, these patients are highly febrile and toxic. The diagnosis is clinical! Do not await confirmatory antibody tests to begin treatment (they will be negative in the acute period). These patients may appear to have meningococcemia. If the clinician is unsure of the diagnosis, it is essential to treat for both diseases. Lumbar puncture in a patient with RMSF will show leukocytosis with 25% neutrophils, elevated protein, and low to normal glucose. If not recognized and treated early, the mortality associated with RMFS is higher than 30%. However, mortality decreases to 5% with prompt appropriate antibiotic therapy. The neurologic deficits are permanent in 15% of cases. Doxycycline is the drug of choice in all nonpregnant patients, even children. Pregnant patients may be treated with chloramphenicol, although doxycycline may also be considered in especially sick pregnant patients because chloramphenicol simply does not work as well.

Secondary Syphilis
Syphilis is an infection caused by the spirochete *Treponema pallidum*. Primary syphilis is characterized by a painless chancre (punched-out base with rolled edges). It resolves completely and without scar formation in about 3 to 6 weeks. Secondary syphilis develops about 4 to 10 weeks after emergence of the chancre. The patient will have many constitutional symptoms: malaise, headache, sore throat, fever, joint and muscle aches, decreased oral intake, meningeal symptoms, generalized lymphadenopathy, and a rash. The rash of secondary syphilis is maculopapular, symmetric, nonpruritic, and diffuse. It may also involve the palms and soles, as well as the oral mucosa. Patients may also have other skin findings, including condylomata lata (painless, gray to white verrucous lesions in the groin and other moist regions) and patchy alopecia. These patients can become very ill, with gastrointestinal distress, hepatitis, arthritis, optic neuritis, proctitis, and nephropathy. The diagnosis is made clinically, and a high index of suspicion is required. Testing for HIV is also recommended. The sensitivity of the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests approaches 100% for secondary syphilis. Because false-positive testing does occur, confirmatory fluorescent treponemal antibody absorption testing (FTA-ABS) is also performed. The sensitivity of FTA-ABS for secondary syphilis also approaches 100%.

Meningococcemia
Meningococcemia is caused by infection with *Neisseria meningitidis*, a gram-negative intracellular diplococci that causes fulminant septicemia and has a predilection for adolescents and children younger than 4 years. Without proper treatment, meningococcemia is invariably fatal; mortality remains at 10% to 20% even with immediate therapy. Patients are ill appearing, febrile, and in shock and have changes in mental status and a rash that develops within 24 hours of toxicity. The rash is initially erythematous and maculopapular (beginning on the wrists and ankles) and then spreads (sparing the palms and soles) and becomes a petechial vasculitis that is palpable. Early in the illness, meningococcemia can be mistaken for RMSF. Treatment of both is mandatory when there is any diagnostic uncertainty. The diagnosis is confirmed by Gram stain and blood or CSF culture. Gram staining of a specimen from a meningococcal skin lesion is more sensitive than a CSF Gram stain (72% versus 22%, respectively). Lumbar puncture in patients with meningitis will show leukocytosis with a predominance of neutrophils, low glucose, and high protein. Complications include disseminated intravascular coagulopathy (DIC), acute respiratory distress syndrome, renal failure, multisystem organ failure, and adrenal hemorrhage (Waterhouse-Friderichsen syndrome). Ceftriaxone is first-line therapy. Vancomycin should be added in cases of diagnostic uncertainty to cover resistant streptococcal meningitis. Dexamethasone has been shown to reduce neurologic sequelae if administered early (before antibiotics, if possible). Rifampin prophylaxis for close contacts is recommended; alternatives include single-dose ciprofloxacin and intramuscular ceftriaxone. A vaccine is available and is now recommended routinely for children 11 to 18 years of age.
VESICULOBULLOUS RASHES

Vesiculobullous rashes provoke significant angst in many physicians; however, the differential diagnosis for febrile and toxic patients can be greatly simplified by discerning whether the rash is localized or diffuse. Ill patients with a diffuse vesiculobullous rash and a fever may have varicella or a more devastating illness such as smallpox or purpura fulminans/DIC. Toxic patients with localizing lesions require evaluation for necrotizing fasciitis (see Table 192.3).

Necrotizing Fasciitis

This acutely toxic disease is caused by group A β-hemolytic streptococci and may also be synergistic with Staphylococcus aureus, Vibrio vulnificus, anaerobes, or polymicrobial infections. Predisposing factors include intravenous drug use, diabetes, malignancy, acquired immunodeficiency syndrome, alcoholism, and other immunosuppressive states. Importantly, these patients have pain out of proportion to the findings on examination and more toxicity than typical for cellulitic disease. Hemorrhagic bullae are often evident superficially, and the disease spreads rapidly along fascial planes. Crepitation may be present and can be seen as subcutaneous gas on radiographs. Treatment is prompt surgical débridement and broad-spectrum antibiotics. Adjunctive hyperbaric oxygen therapy has also been shown to significantly reduce mortality and amputation rates in these patients. Mortality in patients with necrotizing fasciitis ranges from 0% to 75% (average mortality, 35%) and is dependent on the infective organisms, patient population, treatment protocols, and resources (including the availability of hyperbaric oxygen therapy).

Varicella

Chickenpox (varicella-zoster virus or herpesvirus 3) is usually a benign, self-diagnosed infection with an incubation period of 10 to 21 days. Infectivity is present 48 hours before the onset of fever and continues until all lesions have crusted. Symptoms include conjunctival and catarrhal manifestations followed by a rash. The rash appears in various stages at same time (papules, vesicles, crusted) and is described historically as “dew drops on a rose petal.” Children should not be given aspirin for fever because of concerns related to Reye syndrome. All patients should avoid those who are pregnant, elderly, or immunocompromised. Complications from varicella include staphylococcal or streptococcal secondary infections, visceral complications (15% mortality rate in the immunocompromised), neurologic complications (most common in children), pneumonia (most common in adults), and perinatal varicella (30% mortality rate). Prevention involves immunization, which decreases the rate of occurrence and severity. Please refer to Chapter 18 for further review of varicella.

Smallpox

Few differential considerations invoke more fear or dread than smallpox. Although smallpox was eradicated in 1980, isolates still exist in the United States and Russia. Moreover, nearly 50% of the U.S. population has never been vaccinated against smallpox. Infection by the variola virus is manifested in two forms (major and minor), and only humans are infected (no carrier state). It is spread by inhalation or direct contact. Infection results in a silent viremia for 2 weeks, followed by the sudden onset of fever, severe headache, nausea, malaise, and a sore throat. During this time an enanthem that is fine, erythematous, and macular may be found on the posterior pharynx, soft palate, and tongue. It is followed by the enanthem, which begins on the face and spreads centrifugally to encompass the entire body (including the palms and soles in 50%) within 24 hours. These lesions start as macules, then papules, and finally pustules that crust over in several weeks. The lesions are always in the same stage of development. Any suspected cases should be reported to the Centers for Disease Control and Prevention at once. Vaccinated personnel should obtain viral swabs of the patient’s throat or pustular skin lesions. Strict respiratory and contact isolation is mandatory. Supportive care with attention to eye care (keratitis) is indicated. The mortality rate positively correlates with the extent of the rash (10% to 80%; mean, 30%). Death usually occurs as a result of overwhelming toxemia. Complications include blindness and diffuse scarring.

Purpura Fulminans/Disseminated Intravascular Coagulopathy

This acutely life-threatening disorder is associated with previous infection (often meningococcus or gram-negative organisms), sepsis, pregnancy, massive trauma, end-stage malignant disease, hepatic failure, snake bites, transfusion reactions, or anything that can precipitate DIC. It is characterized by fever, shock, rapid subcutaneous hemorrhage (ecchymotic purpura, hemorrhagic bullae), tissue necrosis, widespread petechiae, bleeding from multiple sites, widespread organ failure, and DIC (Fig. 192.4). The pathophysiology of this disease spectrum involves activation of the coagulation cascade with thrombin and fibrin formation. This leads to occlusion of vessels and end-organ damage with the consumption of platelets and clotting factors. Overactivation of the fibrinolytic system then occurs with resultant endogenous fibrinopeptide A production and bleeding. Laboratory findings include thrombocytopenia, schistocytes, prolongation of the prothrombin time (PT) and partial thromboplastin time (PTT), increases in fibrin degradation products and D-dimer levels, and a decrease in fibrinogen levels. The lower the fibrinogen levels, the higher the mortality. Emergency hematology/
Patients with TTP have fever, jaundice, and a diffuse, nonpalpable petechial/purpuric rash in a distinct manifestation. The differential diagnoses include petechiae (most common finding and may involve the palms and soles), and Osler nodes (painful, violaceous nodules in the pulp pads of finger and toes).40 The diagnosis and initiation of treatment. Numerous conditions are associated with TTP, including HIV infection, lupus, pregnancy, malignancy, and transplantation. Drugs associated with TTP include clopidogrel, cyclosporine, and quinine. Laboratory studies reveal that unlike DIC, the PT, PTT, and fibrin level are often normal. Schistocytes and helmets cells are seen on blood smears and indicate hemolysis. The physiopathology of TTP involves platelet aggregation and thrombus formation with diffuse organ and tissue damage. Treatment includes emergency hematology/oncology consultation, plasmapheresis, FFP, ICU admission, and treatment of the underlying cause. Importantly, FFP can be used as a temporizing measure, but patients with TTP should be transferred to a facility with the capability of performing plasmapheresis. Platelet administration is to be avoided because it will precipitate more thrombus formation.41 The mortality associated with TTP is higher than 90% if not properly treated. Exchange transfusion can decrease the mortality to 10%.41,42 Facilities without the ability to perform exchange transfusions must consider emergency transfer to an appropriate facility.

**TREATMENT**

**ERYTHEMATOUS RASHES**

Treatment of these rashes can be found in Table 192.4. These highly lethal rashes require intensive treatment and continuous monitoring for complications. Patients with TEN may benefit from IVIG, although this indication is not yet approved by the FDA. Most physicians recommend against steroid use. Sulfadiazine should not be used on the wounds because sulfa is the most common offending agent.43 Treatment of SSSS in young, well-appearing patients with minimal skin sloughing may be conducted on an outpatient basis (mortality < 5%). By contrast, adult SSSS has a mortality that can be as high as 60%.45 Treatment of Kawasaki disease involves hospitalization, supportive care, and immediate high-dose aspirin to prevent coronary artery vasculitis, coronary vessel aneurysms, myocarditis, and myocardial infarction. Importantly, IVIG must be administered because Kawasaki disease does not respond to antibiotics.5,10 Treatment of erythroderma involves recognition that recovery is long and recurrences common.

**MACULOPAPULAR RASHES**

Treatment of these rashes can be found in Table 192.5. Though rarely lethal, Lyme disease can be associated with significant morbidity, usually related to neurologic and rheumatic complications. Doxycycline is the first-line treatment of Lyme disease in nonpregnant adult patients. Children may be treated with amoxicillin. Ceftriaxone is indicated for those with significant neurologic or cardiac involvement. Treatment of RMSF consists of doxycycline. It is the drug of choice in all nonpregnant patients, even children. Pregnant patients may be treated with chloramphenicol, although doxycycline may also be considered in especially sick pregnant patients because chloramphenicol simply does not work as well.1,15,17-20 Patients with SJS are toxic and have many constitutional symptoms, but the use of steroids is controversial at this time. Meningococcemia is a dreaded disease with many complications. Ceftriaxone is first-line therapy. Vancomycin should be added in...
cases of diagnostic uncertainty to cover resistant streptococcal meningitis. Dexamethasone reduces neurologic sequelae if administered early.

**VESSICULOBULLOUS RASHES**
Treatment of necrotizing fasciitis involves prompt surgical débridement, broad-spectrum antibiotics, and fluid resuscitation. Adjunctive hyperbaric oxygen therapy significantly reduces mortality and amputation rates. Varicella is a self-limited illness in most patients, although complications can be devastating. Treatment of varicella is reviewed in Chapter 18. Smallpox is a devastating illness whose care is primarily supportive, with attention to eye care for keratitis. Death usually occurs as a result of overwhelming toxemia. In a similar manner, purpura fulminans is a disease with high morbidity and mortality. First-line therapy involves treatment of the underlying cause and administration of blood products (FFP, cryoprecipitate, platelets, and red blood cells). Folate, vitamin K, and heparin are also given. Antithrombin III is a promising investigational drug that has not yet been approved by the FDA. A metaanalysis of trials showed a reduction in mortality from 47% to 32% with the administration of antithrombin. Hematologist consultation is essential.

**PETECHIAL/PURPURIC RASHES**
Treatment of RMSF, meningococcemia, and purpura fulminans was discussed in a previous section. Bacterial endocarditis is a disease that requires consultation with cardiology and infectious disease specialists. Treatment consists of broad-spectrum antibiotics to cover MRSA and, thereafter, guidance by culture of blood (three sets) obtained before antibiotic therapy. Treatment of TTP includes ICU admission, emergency hematologic consultation, plasmapheresis, FFP, and treatment of the underlying cause. Importantly, FFP is only a temporizing measure. Patients must be treated definitively with plasmapheresis (exchange transfusion) or be transferred. Platelet administration will precipitate more thrombus formation.

**FOLLOW-UP AND PATIENT EDUCATION**
Most of these illnesses are devastating with significant morbidity and mortality. Invariably, most patients will require close follow-up not only with their primary care provider (PCP) but also with infectious disease specialists, dermatologists, and cardiologists, and some will require surgical interventions.

**ERYTHEMATOUS RASHES**
Patients with TEN require primary care follow-up, wound care, and dermatologic referral. Ophthalmologic consultation is needed for eye involvement. Those infected with HIV also require infectious disease follow-up. Patients with SSSS require PCP follow-up, as well as wound care and referral for any evidence of end-organ damage. Patients recovering from TSS require wound care and PCP monitoring during recovery and surveillance for end-organ damage. Recovery from Kawasaki disease requires PCP follow-up and cardiology referral. Patients with erythoderma require PCP follow-up, dermatologic referral, and wound care. Recovery is long for these patients, and recurrences are common.

**MACULOPAPULAR RASHES**
Patients recovering from SJS require PCP and dermatologic follow-up. Significant mortality and morbidity are associated with SJS, and monitoring for end-organ damage is required. Patients discharged with a diagnosis of either Lyme disease, RMSF, syphilis, or meningococcemia require close PCP follow-up, as well as continued monitoring by an infectious disease specialist.

**VESSICULOBULLOUS RASHES**
Patients with necrotizing fasciitis require continued surgical monitoring, wound care, and possibly adjunctive hyperbaric oxygen therapy. Those in whom varicella is diagnosed require PCP follow-up and wound care as needed. Those with smallpox will require management by an infectious disease physician. Patients with purpura fulminans need continuous, close monitoring with a PCP and a hematologist.

**TIPS AND TRICKS**
Drug reactions: Stop the offending agent and all related compounds at once. This will reduce the risk for death by 30% daily!
Toxic epidermal necrolysis and Stevens-Johnson syndrome: Usually caused by drugs.
Endocarditis, meningococcemia, and Rocky Mountain spotted fever: May be manifested as either a maculopapular (early) or petechial/purpuric rash (late) morphology. Serial examinations are mandatory!
Meningitis: The gold standard for diagnosis is cerebrospinal fluid analysis.
Meningitis prophylaxis: Should be given to close contacts, including classmates, household members, and medical personnel who had contact with respiratory droplets.
Rocky Mountain spotted fever: Doxycycline is the drug of choice, even in children. Pregnant patients may be treated with chloramphenicol, but doxycycline should be considered if the patient is especially ill.
Meningitis versus Rocky Mountain spotted fever: If the diagnosis is not clear, treat both!
Streptococcal toxic shock syndrome: 80% have an associated skin or soft tissue infection. Look for it early because drainage is a critical component of treatment.
Necrotizing fasciitis: Pain out of proportion to findings on examination. Always complete a full genitourinary examination on all ill-appearing patients because many are too toxic to adequately relate symptoms.
Fingers and toes: Must be evaluated for signs of endocarditis (Janeway lesions, Osler nodes, splinter hemorrhages).
Tissue samples: Can be of immense value in certain instances. Tzanck smears are sensitive for herpes infections. Potassium hydroxide preparations can identify yeast infections. Gram stains will identify gonococci and anthrax organisms. Punch biopsies with a Gram stain will aid in the identification of meningococcemia and Rocky Mountain spotted fever.
SECTION XVIII  ▪  CUTANEOUS DISORDERS

PETECHIAL/PURPURIC RASHES
Patients with RMSF or meningococcemia will require PCP follow-up in conjunction with an infectious disease specialist. Those with TTP or purpura fulminans/DIC need close PCP follow-up, as well as close monitoring by a hematologist. Patients treated for endocarditis will require PCP and cardiology follow-up.

CHAPTER 193

The Emergency Psychiatric Assessment

Douglas M. Char

SECTION XIX  EMERGENCY PSYCHIATRIC DISORDERS

KEY POINTS

- The emergency psychiatric evaluation is a focused medical assessment with the primary goal of distinguishing between acute medical and psychiatric conditions.
- Primary mental disorders include disturbances in thought, mood, or personality. The onset of such disorders generally occurs at younger ages.
- Delirium and dementia are causes of global cognitive impairment that may be mistaken for psychiatric disease in emergency department patients, especially the elderly.
- Approximately 50% of patients seeking emergency psychiatric services have a poorly treated or undiagnosed medical illness contributing to their symptoms.
- Provisional diagnoses should drive the need for and extent of diagnostic testing.
- Acute interventions should improve the patient’s cooperation, reduce agitation, prevent secondary harm, and initiate treatment of the primary mental disorder.

PERSPECTIVE

The primary purpose of the emergency psychiatric evaluation is to distinguish between medical and psychiatric causes of disturbed behavior and thoughts. Comorbid medical conditions must be addressed to ensure appropriate and safe admission of patients to a psychiatric facility.

EPIDEMIOLOGY

Cases of psychiatric illness in emergency department (ED) patients have increased 15% in the past decade and now account for 6% of ED visits. Declining inpatient psychiatric beds and limited community mental health resources complicate the care for this population of patients. Pediatric ED visits for psychiatric illness are less well studied, although the predominance of cases occur in the adolescent age group. Suicide prevention is the overriding concern. Teen suicide has tripled since 1950 and is the third leading cause of death in adolescents.2

PATHOPHYSIOLOGY

Controversy surrounds the “medical clearance” process, more appropriately referred to as the “focused medical assessment.” The evidence available to guide emergency practice remains limited and conflicting. Much of the debate revolves around the differing expectations and priorities of emergency physicians (EPs) and psychiatric consultants. The responsibilities of the EP are to obtain an appropriate history, identify the degree of stress, rule out medical cause, recognize the need for developing specific interventions, arrange psychiatric consultation, and plan disposition.3

DEFINITIONS

The fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) distinguishes “mental disorders that are due to a general medical condition” from “primary mental disorders.”4 The terms organic and functional are no longer used to differentiate between illnesses of medical and psychiatric origin (Box 193.1). Clinical practice teaches us that the separation between mental and medical causes is often blurred.

Primary mental disorders include disturbances in thought, mood, or personality. Memory impairment, disorientation, and inattention are rarely features of primary mental disorders.

Delirium and dementia are medical conditions characterized by global impairment in cognitive function. A primary mental disorder may be mistakenly diagnosed in patients with delirium or dementia. It is important to differentiate between these conditions and other psychiatric disorders.

DELIRIUM

The diagnosis of delirium consists of four key elements. (1) Delirious patients have impaired attention and concentration. (2) They demonstrate alterations in consciousness that fluctuate over time. (3) A delirious patient may become acutely agitated or lethargic because of disturbances in the sleep-wake cycle. (4) Abnormal cognition and speech may be apparent.
Sensory perceptions, delusions, and hallucinations are prominent.

The onset of delirium is usually acute, with development over a period of hours to days. Determination of a patient’s baseline cognitive function and onset of symptoms is essential in distinguishing delirium from dementia.

**DEMENTIA**

Pervasive disturbance of cognitive function is the hallmark of dementia. Deficits commonly involve memory, judgment, personality, and language. Patients have no clouding of consciousness. The earliest sign of dementia is subtle memory loss, which may promote anxiety, depression, and psychosis. Patients with dementia may experience an acute worsening of symptoms when stressors overwhelm their intellectual and physiologic reserves. As the disease progresses, patients become less capable of recognizing concomitant medical illnesses (Table 193.1).

</table>
Most patients requiring emergency psychiatric assessment exhibit some form of altered mental status, psychosis, or self-harm. Common psychiatric problems seen in the ED include substance abuse and addiction, affective disorders, anxiety disorders, antisocial personality disorders, and severe cognitive impairment. ED visits for mental health disorders occur when events cannot be managed at home or when caretakers cannot control behavior or provide adequate support.

In addition to cognitive (thought) and affective (mood) disorders, pediatric providers must also be aware of disruptive behavioral or conduct disorders, such as attention-deficit/hyperactivity disorder and eating disorders. These disorders may be the primary reason for the pediatric or adolescent ED visit. Primary mental disorders are usually manifested in patients between 12 and 40 years of age. In older patients, various causes of delirium and dementia are more common than primary mental disorders.

The prevalence of coexisting medical illness in psychiatric patients has been reported to be as high as 50%.

Untreated medical illness often causes deterioration of baseline cognitive function in patients with a known psychiatric disorder. The prevalence of medical disease in patients seen in the ED with an acute exacerbation of an existing mental illness may be as high as 80%. Up to 50% of patients demonstrate a causal relationship between acute medical and psychiatric complaints. Five groups are regarded to be at high risk for medical illness: older patients, patients with history of substance abuse or addiction, patients without a psychiatric diagnosis, patients with preexisting medical disorders, and patients from a lower socioeconomic level.

The EP must answer six key questions during the focused medical assessment:

1. Is the patient stable or unstable?
2. Is the behavior the result of an underlying medical illness?
3. What is the severity of the primary mental disorder?
4. Is psychiatric consultation necessary?
5. Does the patient need to be detained to facilitate emergency treatment?
6. What capability does the psychiatric facility have to treat medical conditions?

**HISTORY**

A focused history of the present illness that reviews current symptoms, elicits precipitating circumstances, assesses risk severity, and establishes a time course should be obtained. Critical historical elements include past medical and psychiatric illnesses, medication use (Table 193.2), substance abuse or addiction, and a family history of psychiatric illnesses.

Patients with cognitive or affective disorders are often unable to provide a coherent clinical history. Friends, family members, and prehospital providers are useful sources of additional information. The patient’s baseline cognitive function may be obtained from the medical record or solicited through discussion with primary care providers.

For children and teens, the history should concentrate on the precipitant of the mental health crisis. Particular areas to review include school performance, relationship with family and peers, living situation, family composition, sexuality, and neighborhood environment. When developmentally appropriate, the history should be obtained from both the child and the caretaker. Up to 20% of adolescents have a serious behavioral or medical problem.

**PHYSICAL EXAMINATION**

An organized and thorough physical examination should be performed. Cursory examination of psychiatric patients is unacceptable. Uncooperative or fully dressed patients may hide weapons, illicit drugs, evidence of physical abuse, or signs of medical illness. Younger patients are more likely to receive a cursory examination.

The patient’s vital signs should be scrutinized for evidence of shock, metabolic derangement, or infection. Search for signs of impaired organ and tissue perfusion. Check for hypoxia and abnormal respiratory effort. Look for abrasions or contusions that may represent recent trauma or unsuspected head injury. Identify subtle, focal weakness or neglect suggestive of possible neurologic impairment. Evaluate for other signs of neurologic disease, including dysesthesia (distortion of sense), apraxia (loss of the ability to carry out purposeful movements), agnosia (inability to recognize sensory stimuli), left-right disorientation, aphasia, or an inability to follow commands. Sensory illusions can be associated with neurologic conditions or intoxications. Visual, tactile, and olfactory hallucinations are generally attributable to medical disease (Table 193.3).

The mental status examination is critical and should assess the patient’s level of consciousness, appearance, behavior, mood, affect, language, thought form and content, perceptions, and cognition. Much of this information can be obtained indirectly by observing the patient during the interview. Standardized assessment tools such as the Folstein Mini-Mental Status Examination (MMS) or the Quick Confusion Scale (QCS) allow detection of subtle deficits (Tables 193.4 and 193.5). Given the demands of a busy ED, many EPs find administering a formal MMS impractical—abbreviated tools are often preferred. Scores of less than 12 on the shorter QCS six-question battery have been shown to correlate with impaired cognition.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Patients with disturbed behavior or thought processes should be presumed to have a medical origin of their condition. Patients with chronic illnesses such as thyroid disease, diabetes mellitus, reactive airway disease, heart failure, stroke, and dementia may have a sudden and dramatic impairment in cognition or affect. Life-threatening causes of delirium should be considered in all patients with psychiatric disturbances. Primary mental disorders should be diagnosed only after serious medical conditions have been convincingly excluded (Box 193.2).

Diagnostic criteria such as those provided in the DSM-IV aid in establishing a provisional psychiatric diagnosis in the ED. Although standardized criteria are useful, interrater agreement among emergency psychiatrists is variable.

Multiaxial diagnoses serve to organize complex clinical information and acknowledge the interplay of medical and psychiatric disease. Axis I diagnoses reflect mental disorders,

axis II diagnoses identify personality disorders, axis III diagnoses include general medical conditions, and axis IV and V diagnoses include psychosocial stressors and adaptive functioning (Fig. 193.1). When evaluating children and teens, complaints should be considered within the context of their physical and social developmental stage.

**DIAGNOSTIC TESTING**

A commonly held belief is the presumed inability of psychiatric patients to relate an accurate history or report signs and symptoms to guide testing. No literature supports this view. Directed testing based on patient complaints is often appropriate.

No standardized or widely accepted ED protocol exists for performing a focused medical assessment of psychiatric patients. Differentiation between medical and psychiatric disease is best accomplished by a detailed history and physical examination. However, it should be noted that many psychiatric facilities have limited medical diagnostic capabilities and that the ED assessment may be the only medical evaluation and source of laboratory testing or imaging that the patient receives.

Screening tests commonly ordered as part of the emergency psychiatric evaluation include pulse oximetry, complete blood count, chemistry panel with glucose, electrocardiogram, urine toxicology screen, urine pregnancy testing, and serum alcohol level. Testing of liver and thyroid function, as well as computed tomography imaging of the brain, should be based on the history (or previous diagnosis) and findings on physical examination. Chest radiography, lumbar puncture, arterial blood sampling, and electroencephalography are rarely indicated as screening tests in the evaluation of patients with suspected psychiatric illness.12,13

The 2006 American College of Emergency Physicians (ACEP) clinical policy “Critical issues in the diagnosis and management of the adult psychiatric patient in the emergency department” posed three questions related to diagnostic testing14:

1. What testing is necessary to determine medical stability in alert, cooperative patients with normal vital signs, a noncontributory history and physical examination, and psychiatric symptoms?

2. Do the results of a urine drug screen for drugs of abuse affect management in alert, cooperative patients with normal vital signs, a noncontributory history and physical examination, and a psychiatric complaint?

3. Does an elevated alcohol level preclude the initiation of a psychiatric evaluation in alert, cooperative patients with normal vital signs and a noncontributory history and physical examination?

EPs are frequently asked to perform detailed screening laboratory and radiographic testing to exclude any medical illness that may be causing or contributing to the patient’s psychiatric symptoms. Early studies of the coexistence of

Fig. 193.1  Multiaxial diagnosis data from the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM). (From First MB, Frances A, Pincus HA, editors. DSM-IV-TR handbook of differential diagnosis. Arlington, Va: American Psychiatric Association; 2002.)
medical illness in patients with psychiatric symptoms argued for the routine use of laboratory testing, although they did not specify which components of the history and physical examination were included or performed on all patients.\textsuperscript{14} These studies involved patients admitted directly to mental health facilities without a medical screening examination. When routine testing is performed, abnormal results are often clinically insignificant.\textsuperscript{3,15,16} Patients who are delirious, have abnormal vital signs, or display altered cognitive states mandate more extensive evaluations. The 2006 ACEP consensus panel noted that routine laboratory testing is of limited utility in teens and younger adults. The value of routine laboratory testing in younger children with psychiatric symptoms has not been studied in ED populations.\textsuperscript{2}

EPs and emergency psychiatrists often disagree on the necessity for a urine toxicology screen as part of emergency focused medical assessment. Although many surveyed EPs find a urine drug screen to be unnecessary, psychiatrists may use the test to determine a cause of the patient’s symptoms or aid in disposition and long-term care of a patient.\textsuperscript{15,16} Retrospective studies suggest that the sensitivity of routine toxicologic testing for the diagnosis of a medical cause of isolated psychiatric complaints is just 20%.\textsuperscript{19} Schiller et al. prospectively tested approximately 400 patients and found no difference in terms of inpatient or outpatient disposition or hospital length of stay.\textsuperscript{17} The ACEP recommends against routine testing for drugs of abuse in alert, awake, cooperative patients. They acknowledged that receiving psychiatric facilities often require such testing but urged that testing not delay psychiatric assessment or admission or transfer.

Acute intoxication may impair the ability to conduct a comprehensive psychiatric examination. It can also mimic or alter psychiatric symptoms and delay proper patient disposition. Psychiatric facilities will often refuse the transfer of intoxicated patients. No data have been found to support a specific blood alcohol concentration at which psychiatric evaluation can be accurately initiated. Adequate decision-making capacity is often unrelated to the patient’s serum ethanol level. Cognitive function should be assessed on an individual basis. The consensus panel recommended that the patient's cognitive abilities, rather than a specific blood alcohol level, be the basis on which clinicians initiate psychiatric assessment.

Diagnostic testing of psychiatric patients in the ED should accomplish one of the following goals: (1) detect or exclude the presence of a condition that has treatment consequences, (2) determine the relative safety or appropriate dose of potential alternative treatments, or (3) provide baseline information useful for monitoring response to treatment. ED protocols should be based on local disease prevalence, common clinical findings, the potential for needed treatment, and the likelihood of admission or extended monitoring. In some states, emergency medicine and psychiatry organizations have created consensus guidelines regarding ED medical assessment of psychiatric patients in an effort to reduce unnecessary resource utilization.\textsuperscript{3}

A few studies have suggested that it may be possible to identify patients with psychiatric complaints who can safely bypass the traditional ED focused medical assessment and be directed for primary psychiatric evaluation.\textsuperscript{20,21} These studies suggest that patients must be alert with normal vital signs, not be under the influence of drugs or alcohol, and have a history of psychiatric illness that is consistent with their current symptoms. The availability of immediate online medical control is critical.

### TREATMENT

Acute behavioral disturbances mandate emergency care that is time and resource intensive. Treatment should be directed at the underlying cause of the disordered thought process or behavior, if known. Emergency psychiatric interventions are guided by three principles: (1) improve patient cooperation, (2) reduce agitation, and (3) reduce the risk for secondary harm.

Patient and staff safety is of paramount importance. Suicidal patients need to be monitored closely and protected from self-harm. Agitated patients constitute a threat to themselves and to others. Rapid administration of psychotropic or anxiolytic medications (or both) is a safe and effective method for controlling potentially dangerous patients. Seclusion, sitters, and the use of physical restraints may be required temporarily. Chapters 194 to 197 provide specific treatment recommendations for psychotic, violent, and suicidal patients. Disease-appropriate treatments of the various causes of delirium and dementia are reviewed elsewhere in this text.

### FOLLOW-UP AND NEXT STEPS IN CARE

The emergency psychiatric focused medical assessment should result in one of four outcomes: (1) a medical cause of the chief complaint is identified, (2) a primary mental disorder is suspected, (3) the symptom or condition is self-limited and resolves, or (4) the cause of the abnormal behavior or disordered thought process remains unclear and mandates further evaluation (medical admission) (Box 193.3).

Patients without an apparent medical cause of their confusion, disordered thought, or bizarre behavior require psychiatric evaluation. Most of these patients will probably need to be admitted to a psychiatric service for extended observation and therapy. Some individuals may need to be held involuntarily according to individual state laws.

Discharge may be considered for patients whose symptoms resolve rapidly after minimal treatment or after a short period of observation. Three discharge criteria must be

---

**BOX 193.3 Potential Outcomes of the Emergency Psychiatric Evaluation**

A medical cause of the abnormal behavior or thought process is identified and treatment is initiated.

A primary mental disorder is suspected and psychiatric consultation is obtained.

The patient’s condition is self-limited and has resolved. Discharge criteria are met.

The cause of the abnormal behavior or disordered thought process remains unclear. Further evaluation mandates admission to a medical service with psychiatric consultation.

</tr>
</tbody>
</table>

met: (1) patients should be able to care for themselves or should have an appropriate caregiver at home, (2) patients cannot be actively suicidal or homicidal, and (3) patients should not have any unresolved symptoms of an acute medical illness.

If subacute medical conditions are identified in patients requiring psychiatric admission, the accepting psychiatric service must be capable of providing appropriate care and follow-up. Untreated medical illnesses may complicate psychiatric interventions and result in repeated visits to the ED (Table 193.6).

REFERENCES

Psychosis describes syndromes that impair both thought content and thought process. Disturbances in thought content include perceptions that are not based in reality, whereas disturbances in thought process reflect thoughts that are disorganized and illogical in form. Psychotic symptoms include visual, tactile, or olfactory hallucinations; delusions; impairment of concentration and attention; and disorientation. Schizophrenia is the disorder that is most often associated with psychosis. Bipolar disorder, major depression, and substance abuse are examples of psychiatric diagnoses that can also cause symptoms of acute psychosis.

The 1-year prevalence of the schizophrenic disorders is 1.1%. One in every 100 persons in the United States suffers from psychotic symptoms. Episodes of psychosis are generally precipitated or exacerbated by psychosocial stressors. Psychosis may be acute or chronic. As is often the case with the first manifestation of schizophrenia, acute psychotic episodes prompt patients to seek emergency care for their bizarre behavior or troubling perceptions.

PATHOPHYSIOLOGY

The dominant theory used to explain the pathophysiology of psychotic thought is the dopamine hypothesis. This theory suggests that psychosis is probably the result of excessive dopamine transmission in the mesolimbic pathway of the brain. Evidence offered for the behavioral influence of this neurotransmitter is based on the observed effects of antipsychotic medications on dopamine pathways of the brain. Dopamine receptor antagonists (D2 receptor antagonists) improve disturbed thoughts in psychotic patients. The efficacy of the typical (first-generation) antipsychotic agents depends on the degree to which these drugs block D2 receptor activity.

Competing theories that describe the pathophysiology of psychosis are also based on neurotransmitter activity. These theories generally cite the effects and interplay of serotonin and glutamate with dopamine.

Most psychotic disorders are initially manifested in adolescence and young adulthood. The median age at the onset of symptoms of a psychiatric disorder is 16 years. By the age of 38 years, symptoms will have developed in more than 90% of patients with a mental disorder. The typical example of a newly psychotic patient is a young person brought to the emergency department (ED) by family or friends who are concerned about the patient’s bizarre behavior or unusual beliefs. The “positive” symptoms of psychosis, including hallucinations and delusions, are often more obvious and distressing than the “negative” symptoms, which are affective and generally develop more insidiously.

The key features of psychotic symptoms are perceptions and beliefs that are not based in reality. Such disturbances include hallucinations, illusions, and delusions.

Hallucinations are sensory perceptions that are apparent only to the patient experiencing them. Auditory hallucinations are the most common and are typically described as hearing voices of people who are not present. Hallucinations that involve other senses (visual, olfactory, or tactile) are less frequently reported and may be the result of medical illness. Patients who are hallucinating appear to be preoccupied or distracted as they respond to internal stimuli.
Illusions refer to misperceptions about a patient’s surroundings, whereas hallucinations are wholly internal and are not prompted by an environmental stimulus. Delusions are misinterpretations of events or perceptions that lead psychotic patients to erroneously attribute experiences to unlikely or bizarre beliefs. Unlike cultural beliefs, delusions are explanations that are not shared by others. Most delusions involve a sense of control. For example, patients with delusions of persecution may believe that they are under hostile surveillance or that people are plotting against them. Grandiose delusions cause patients to believe that they are endowed with supernatural powers or are able to affect events outside their sphere of influence.

Psychosis may also be manifested as disorganization in thought process, with patients expressing ideas and words that are not coherently linked. Thoughts are described as tangential when the patient switches from one topic to another without logical association. When thoughts become more disorganized, the patient may start using neologisms, or self-created nonsense words. Speech may later regress into an incomprehensible jumble of unassociated phrases that may be described as a word salad.

The negative symptoms of psychosis reflect a loss of function, such as the ability to express affect, generate speech, or become motivated. These symptoms may be overlooked because they are often perceived as less obviously disturbing than “positive” symptoms, but they can also significantly impair the lives of psychotic patients.

DIFFERENTIAL DIAGNOSIS

First manifestations of psychosis are uncommon in young children and older adults; delirium or dementia should not be confused with true psychotic behavior. Causes of delirium may become evident through abnormal vital signs or subtle findings on physical examination, either of which should prompt a search for medical conditions that may mimic psychiatric disease. Examples of medical causes of delirium that may be mistaken for psychosis include ingestion of toxins, substance abuse, and brain tumors. Additionally, certain medical conditions may precipitate psychosis or exacerbate chronic underlying mental disorders.

D2, Dopamine 2; IM, intramuscularly; IV, intravenously; PO, orally.
*Administration of haloperidol intravenously is off label because of the risk for QT prolongation and arrhythmia.
†A “black box” warning was mandated by the Food and Drug Administration in 2001 given the risk for fatal tachyarrhythmias.

DIAGNOSTIC TESTING

A detailed discussion of the emergency psychiatric evaluation can be found in Chapter 193.

PSYCHOTROPIC MEDICATIONS

TYPICAL (FIRST-GENERATION) ANTIPSYCHOTIC AGENTS

Typical antipsychotic medications have high affinity for D2 receptors, thus blocking dopamine overactivity in the mesocortical pathway. D2 antagonism accounts for the clinical profile of these agents, which are useful in treating the positive symptoms of schizophrenia, namely, hallucinations and delusions.2 Haloperidol (Haldol) is the prototypic agent of this drug class (Table 194.1).

Typical antipsychotic agents also decrease dopaminergic activity in the nigrostriatal pathway at therapeutic doses. This adverse effect leads to increased cholinergic activity, which promotes extrapyramidal symptoms (EPSs) such as dystonia, akathisia, and other movement disorders. Tardive dyskinesia is thought to arise from upregulation ( supersensitivity) of postsynaptic dopamine receptors in the nigrostriatal pathway after prolonged receptor blockade. Concomitant administration of benztropine (Cogentin) may slow the development of EPSs.

ATYPICAL (SECOND-GENERATION) ANTIPSYCHOTIC AGENTS

Atypical antipsychotic medications have higher affinity for serotonin (5-HT2A) receptors than for D2 receptors. Serotonergic neurons in the dorsal raphe nuclei interact with dopaminergic neurons in the nigrostriatal pathway and modulate the clinical effects. Atypical antipsychotic agents are characterized by a lower incidence of EPSs and show a diverse range of binding activities at other receptor sites as well. Serotonin and other neurotransmitter blockade may account for the beneficial effects of atypical antipsychotic agents against negative behavioral symptoms by increasing dopamine activity in the prefrontal cortex (Table 194.2).
Rapid Used to increased impulsive behavior with benzodiazepine use doses. Rare reports have noted “frontal disinhibition” leading in patients with previous head injury or mental retardation. Psychotic agents has been shown to provide superior results. Combination therapy using benzodiazepines with typical antipsychotic medications to sedate agitated or violent patients. An added benefit of the administration of benzodiazepines is the treatment of alcohol withdrawal if that is the cause of the agitation. Adverse effects, including oversedation and diminished respiratory drive, are minimal at low doses. Rare reports have noted “frontal disinhibition” leading to increased impulsive behavior with benzodiazepine use in patients with previous head injury or mental retardation (Table 194.3).

**PARTIAL RECEPTOR AGONISTS**

Partial receptor agonists demonstrate variable clinical effects, as influenced by the receptor-binding affinity of the agent and the patient’s endogenous levels of neurotransmitter. One available partial agonist, aripiprazole (Abilify), appears to be an effective and possibly a superior treatment option for patients with schizophrenia. It does not completely block the mesolimbic system (associated with “negative” symptoms and cognitive impairment), nor does it completely stimulate the nigrostriatal or tuberoinfundibular pathways responsible for EPSs and elevated prolactin levels. Aripiprazole thus has a low side effect profile and is taken orally at a dose of 10 to 30 mg/day.

**BENZODIAZEPINES**

Benzodiazepines are commonly used to treat psychotic agitation because of their efficacy and tolerability. These agents increase the effects of γ-aminobutyric acid (GABA) on the chloride ionophore of the GABA-benzodiazepine receptor complex, thereby causing sedation and sleepiness. Benzodiazepines are generally administered in combination with typical antipsychotic medications to sedate agitated or violent patients. An added benefit of the administration of benzodiazepines is the treatment of alcohol withdrawal if that is the cause of the agitation. Adverse effects, including oversedation and diminished respiratory drive, are minimal at low doses. Rare reports have noted “frontal disinhibition” leading to increased impulsive behavior with benzodiazepine use in patients with previous head injury or mental retardation (Table 194.3).

Combination therapy allows rapid, safe sedation, in addition to control of the psychotic features.

Any agitation or violent behavior associated with psychosis should be managed as soon as a patient arrives in the ED. Verbal warnings should precede the use of chemical or physical restraint. The least restrictive method of restraint is preferable to facilitate a safe and complete diagnostic evaluation.

**DISPOSITION**

In many jurisdictions, patients may be held against their will by police officers or attending medical staff if they are determined to be gravely disabled, a danger to themselves, or a danger to others because of a mental disturbance. The goal of involuntary restraint is to provide treatment that may improve the patient’s decision-making capacity and allow time for evaluation of any undiagnosed illnesses. Patients may be discharged from the ED if their psychotic behavior is well controlled, if medical and surgical concerns are addressed, if they have accompanying family or friends, and if aftercare is readily available.

**REFERENCES**

REFERENCES

The goal of caring for a violent patient is first to protect everyone involved and also to diagnose and treat important medical and psychiatric conditions (see the “Priority Actions” box). These goals are best achieved if warning signs of violence are recognized and the safest and most effective means of behavioral control are used.

The epidemiology of violence in the emergency department (ED) is inexact; past surveys suggest that as many as 80% of events are unreported. Still, clear evidence indicates that most EDs experience violent patients routinely. Of greater concern, ED caregivers are often victims. More than 70% of ED nurses have reported being the victim of physical violence during their career. The rate of assault on health care workers is 8 per 10,000, as compared with 2 per 10,000 for all private-sector industries, with the ED being one of the highest-risk areas.

Violence may range from verbal threats to physical assault. Of reported events in one survey, 90% of cases involved the patient and 10% involved family or visitors. A few staff members may be confronted by former patients outside the ED or may become victims of stalking.

Nearly 60% of EDs in the United States have reported an armed threat on a staff member within 5 years. Weapons may be carried by patients, family members, visitors, or even staff members. Patients most likely to carry weapons include those with schizophrenia or paranoid ideation and individuals who have been the victims of gunshot wounds. Many violent patients are intoxicated with alcohol or drugs.

Violence threatens the career longevity of ED staff. Violent events should be regularly reported to police and hospital administration to raise awareness of this societal problem and to encourage safer practice environments.

**Patient risk factors for violent behavior** include evidence of agitation (e.g., pacing), substance abuse, a previous history of violence, arrival at the emergency department in police custody, and male gender.

**Disarming protocols and deescalation techniques** are critical methods for prevention of violence.

**Agitated or violent behavior** is frequently caused by medical conditions, such as hypoglycemia or intoxication.

**Violent patients** should be given a verbal warning before they are restrained. Physical restraint should be supplanted by chemical restraint when safety allows.

**Medical complications of incorrect or prolonged physical restraint** include hyperthermia, acidosis, rhabdomyolysis, and death.

**Sedation should be tailored to the suspected cause** of the agitation, as well as the desired depth and length of sedation.

**A combination of an intramuscular benzodiazepine (lorazepam) and a butyrophenone (haloperidol) provides consistent sedation for many causes.**

**Goals for the Care of Violent Patients in the Emergency Department**

Recognize risk factors and warning signs before violence occurs.

Use deescalation (communication) techniques to prevent violent behavior.

Control the patient and situation to minimize further violence.

Diagnose and treat reversible causes of agitation.

Protect the patient and others through appropriate restraint methods.

**Violent behavior rarely erupts without warning.** Risk factors for violence include an escalating psychiatric illness (e.g., schizophrenia, personality disorders, mania), alcohol and drug abuse, a previous history of violence, arrival at the ED in police custody, and male gender (Box 195.1). The use of risk factors to predict violent behavior has not been tested in cohorts of emergency physicians; psychiatrists have been only 60% accurate in predicting violence when using risk factors alone.
BOX 195.1 Risk Factors for the Use of Concealed Weapons and Violent Behavior in the Emergency Department

**Concealed Weapons**
- Schizophrenia
- Paranoid ideation
- Victims of gunshot wounds

**Violent Behavior**
- Schizophrenia
- Personality disorders
- Mania
- Substance abuse or intoxication
- Previous history of violent behavior
- Arrival in police custody
- Male gender

Verbal and nonverbal clues provide evidence of impending violence. As patients become more agitated, the level of their voice may rise and their hand gestures may be more pronounced and expressive. Patients may exhibit restlessness on their gurney or may pace. Providers should trust their instincts when they become uncomfortable with an agitated patient. Emotional stress, prolonged waiting times, and gaps in communication create a provocative and unsupportive environment.

**INTERVENTIONS**

Standardized methods should be used to confiscate concealed weapons. Metal detectors are used in some EDs and are recommended when possession of weapons by patients or visitors is frequent. For patients, a policy of routine undressing and gowning will minimize the likelihood of using hidden weapon when performed in an unbiased manner, regardless of the chief complaint.

Preparation of the examination room can facilitate safety. As many objects as possible should be removed from examination rooms that routinely hold violent or agitated patients. Panic buttons should be available for use by staff in any room where agitated patients are interviewed. Ideally, examination rooms should have two exits so that neither the clinician nor the patient feels trapped. Restless patients may become more agitated when physical outlets are constrained, so both the patient and caregiver must have unobstructed, rapid egress. Staff members should remove personal objects that could be used to cause injury by an assaultive patient. Such objects include neckties, large dangling earrings, and stethoscopes kept around the neck.

**DEESCALATION TECHNIQUES**

Early attention and preferential treatment may defuse anger born of impatience. If at triage, an agitated patient should be taken directly to a treatment room. Volatile patients should be removed from contact with other persons to decrease stimuli and avoid tension.

Essential violence prevention techniques include interpersonal skills that convey respect and unconditional positive regard. Improper behavior does not have to be accepted by ED staff, but no disrespect to the person should be conveyed. Start by stating explicitly that "this emergency department is a safe place" and the patient will be cared for well. Make the patient physically comfortable. Offer food or drink both as an expression of caring and also to minimize irritability. Do not surprise the patient; announce your arrival with a knock on the door or a verbal greeting. Ask permission to touch the patient before doing so. When speaking to the patient, use a calm and soothing voice. Listen attentively and intuitively to overwords and actions while attempting to assess underlying motivations and driving impulses. Additionally, listening will reassure the patient, and it is a caring act. Use straightforward speech and always be honest.

Even as the person receives genuine, unconditional care, boundaries of acceptable behavior should be set and consequences must be consistent. Inappropriate behavior is unacceptable and patients should be told the ramifications. Some patients do not have the ability to cope with the stressful environment and become verbally or physically uncontrolled. Other patients respond to limit setting and rules. Most require anxiolytics. Early use of a low-dose benzodiazepine often helps patients cope and prevents later escalation. No action or treatment should ever be punitive. Chemical restraint, physical restraint, seclusion, and arrest are predictable consequences of inappropriate behavior, but early medical therapy is compassionate and usually prevents escalation.

**TIPS AND TRICKS**

**Deescalation Techniques Useful for Prevention of Violence in the Emergency Department**

**Do**
- Disrobe and gown all patients regardless of the chief complaint.
- Disarm all patients at triage through the use of metal detectors.
- Remove dangerous objects from the examination room.
- Remove personal objects that can be used as weapons (tie, stethoscope).
- Provide preferential, timely, and attentive care.
- Make the patient comfortable (offer food, blankets).
- Ask permission to enter the room and to examine or touch the patient.
- Use a calm voice.
- Explain anticipated waits, delays, and testing.
- Set limits and ramifications for inappropriate behavior.

**Do Not**
- Block exits from the examination room.
- Shout or yell at patients.
- Argue or challenge patients.
- Allow your emotions to overcome your judgment and behavior.

Health care providers can escalate a patient’s behavior through their own instinctive, impulsive, natural human conduct. Anger or frustration should never inspire unprofessional behavior or decisions. Physical and emotional distance
may minimize the emotional reactions. A buffer zone of at least four body widths between the provider and the patient is recommended.

When a caregiver feels the urge to shout, argue, or engage in a staring match with a patient, the caregiver is inadvertently reciprocating the violence of the patient. Controlling these natural instincts is an important professional skill that for many requires cultivation and practice. Other caregivers must cultivate a willingness to engage sufficiently because their instinct is to disengage. Too much distance can be equally detrimental. Finding the optimal emotional and physical distance to be effective and caring is a practiced art. If caregivers are too distant, they will be aloof, condescending, or disengaged. If caregivers are too close, they may become stimulated by the patient’s disorder. The right distance enables control and effectiveness.

### MEDICAL CLEARANCE

Agitated or violent behavior is frequently caused by treatable medical conditions. Reversible causes of altered mental status and violent behavior should be considered during the initial evaluation of the patient. Such causes include substance abuse, intoxication, glucose abnormalities, hypoxia, trauma, abnormal temperature (hypothermia and hyperthermia), infection, stroke, hypertension, and seizures. Older adults with new agitated behavior, delirium, or psychosis should undergo an extensive inpatient medical evaluation before a first-time psychiatric unit admission.

### TREATMENT

**PHYSICAL RESTRAINT**

**Rationale**
The use of restraint is indicated when verbal attempts have failed and action must be taken to prevent injury to the patient or staff. Restraint should be used only to facilitate diagnosis and treatment. It is inappropriate to use restraint as punishment or simply to quiet a disruptive patient.7

The Supreme Court case Youngberg v. Romero 1982 provided exception from assault statutes for physicians who restrained patients to protect the patient or others. This physician decision must be made carefully, as rarely as possible, and only under compelling circumstances to ensure safety.

The Joint Commission has published clear guidelines regarding monitoring, documentation, and the application of physical restraint (Box 195.2). Protection of the patients’ rights, dignity, and well-being is of utmost importance. The decision to apply physical restraint should be assessment driven; the provider must evaluate the individual patient in some way before a restraint is applied. It is inappropriate to maintain standing protocols. The selection of restraint should be individualized, and the least restrictive method is preferred; for instance, it is not necessary to restrain an agitated elderly patient with dementia in the same manner as an aggressive, muscular patient with cocaine intoxication. Hospitals must provide adequate training such that competent staff members are available for the safe application of physical restraint at all times.

### BOX 195.2 Guidelines for the Application of Physical Restraint

- Protect the patient’s rights, dignity, and well-being. Use of restraint is assessment driven. Use the least restrictive method.
- Trained, competent staff should provide safe application of restraint.
- A time-limited order must be noted on the chart. Document why restraint is necessary—be specific. Protect yourself and others. Act in the best interests of the patient.
- Use restraints to facilitate medical evaluation or treatment. Nursing documentation should be very thorough.
- Monitoring and reassessment of the patient’s clinical condition and needs are essential.

### BOX 195.3 Systematic Process for the Application of Physical Restraint

- Minimize physician involvement if possible.
- The restraint team consists of four members and an identified leader:
  - The restraint team enters together.
  - The restraint team is professional and nonthreatening.
  - The leader is at the head of the bed.
  - The leader explains the process to the patient.
- Limbs are controlled by contact at the major joints. Restraints are attached to the solid frame of the gurney.

**Documentation**

Documentation differs for physicians and for nursing staff. A time-limited order for restraints must be written on the chart before or shortly after restraints are applied. Providers must document why physical restraints were necessary and must cite that verbal techniques failed to calm the patient. Be specific about the patient’s condition and reasons for restraint, including potential danger to the patient or others, the planned medical evaluation or treatment, and assessment of the patient’s decision-making capacity. Nursing responsibilities include monitoring, frequent reassessment, and documentation of the patient’s condition and personal needs. The advent of electronic medical records and computerized physician order entry presents an opportunity to direct documentation that better meets regulatory requirements.

**Technique**

Safe application of physical restraint is best achieved through systematic, consistent, protocol-driven techniques (Box 195.3). Many hospitals have a restraint team of at least five members who respond to the bedside when called by any
The violent patient

Restraint

Physician
Document why physical or chemical restraint was chosen and necessary. Cite that verbal techniques failed to calm the patient.

Record specific information about the patient’s arrival, the reasons for restraint, the potential danger to self or others, the planned medical evaluation, and an assessment of the patient’s decision-making capacity.

Record the initial evaluation by a licensed, independent provider within 1 hour of the patient’s arrival and restraint.

A time-limited order should be charted within 1 hour of the patient’s arrival.

Update restraint orders every 4 hours for adults, 2 hours for adolescents aged 9 to 17 years, and 1 hour for children younger than 9 years.

Nursing
Frequently reassess the patient’s vital signs, condition, and personal needs.

Patients should then be reassessed every 15 minutes for the following:

- Signs of injury associated with the application of restraint
- Nutrition and hydration
- Circulation and range of motion in the extremities
- Vital signs
- Hygiene and elimination
- Physical and psychologic status and comfort
- Readiness for discontinuation of restraint

*Refer to www.jointcommission.org for more information.

Types of Physical Restraint

The type of physical restraint used is frequently institution specific. Leather and soft cloth restraints are the types most commonly applied to the limbs. Leather restraints are difficult for the patient to remove and rarely compromise the distal circulation; however, they require a special key to remove and are difficult to cut off in an emergency. Soft cloth restraints may tighten as the patient struggles against them, thus causing circulatory compromise. In contrast to leather restraints, soft cloth restraints are simpler for staff to remove by untying knots or cutting with trauma shears. Vest and waist restraints (“posies”) are useful for elderly patients who are at risk for wandering or falls but who not need their limbs restrained.

Positioning

Restraint position may be changed depending on the patient’s clinical status and the needs of the staff. Restraining a patient in the supine position is more comfortable for the patient and allows greater ease of examination. Patients with an increased risk for aspiration should be restrained on their side. Patients should not be restrained in a “hog-tied” position (Fig. 195.1). Agitated patients are able to generate significant force and momentum and have been known to overturn gurneys if they are not restrained in the proper position. If all four limbs are to be restrained, the patient should have one arm up and one arm down. When only two limbs are restrained, the contralateral arm and leg should be restrained. It is more difficult to generate enough force to overturn a gurney in these positions (Fig. 195.2).

Special situations may arise when additional or alternative restraint is indicated. A sheet may be placed across the patient’s torso and tied to the gurney as a chest restraint when movement of a patient’s torso increases the risk for fall or injury despite the use of four-point limb restraint. Extra attention should be paid to the patient’s respiratory status if a chest...
restraint is added. A firm cervical collar, such as a Philadelphia collar, may be applied to patients who bite. Some providers advocate greater patient comfort by tying the lower extremity to the contralateral bed rail. This allows more movement of the legs while preventing external rotation and extension of the knee for deriving more kicking power.

In the rare case of a patient who is loose in the ED or hospital with a knife or a needle-syringe assembly, a mattress may be used to push the patient into a wall, or two mattresses may be used to sandwich the patient and thus prevent injury to the patient, staff, or innocent bystanders.

Complications
Abrasions and bruising account for the majority of complications resulting from restraint. However, serious complications and death can occur if restraints are applied inappropriately or the patient is not adequately monitored.

One small subset of physically restrained patients, usually accompanied by law enforcement, suffers cardiac arrest shortly before or after arrival at the ED. For many years their demise was attributed to positional asphyxia related to the prone or hobble position. Positional asphyxia results from an alteration in respiratory mechanics with ensuing decreased pulmonary function and increased cardiac output caused by the patient’s position. This change in pulmonary function is not clinically relevant in normal volunteers subjected to prone restraint, however. More recent studies have found that factors related to the excited delirium are more likely to contribute to sudden death in these restrained individuals. Protracted struggle against physical restraint by patients with altered pain sensation may complicate or lead to hyperthermia, increased sympathetic tone with vasoconstriction, and release of lactic acid from prolonged isotonic muscle contractions. Profound metabolic acidosis is associated with cardiovascular collapse in many restraint-related deaths. Cocaine and other sympathomimetic intoxications are frequently seen in this patient population.

Patients delivered to the ED who are restrained in a prone or hobble position should be turned onto their side. Patients who have been struggling against restraint should receive aggressive fluid resuscitation while evidence of associated metabolic acidosis or rhabdomyolysis is excluded. Aggressive chemical sedation should be administered to patients who continue to struggle against physical restraint.

CHEMICAL RESTRAN, ANXIOLYSIS, AND SEDATION
Rationale
Chemical restraint is the administration, generally involuntarily, of medications to control a patient’s dangerous behavior. Ideally, before violent behavior erupts, patients should be offered voluntary treatment with anxiolytics or sedatives to prevent the need for acute, involuntary behavioral control. Patients with the potential for violence often go to the ED voluntarily because they know that they need help and treatment. Experienced, wise caregivers offer an anxiolytic when it is evident that patients have poor self-control and a propensity for violence. Early provision of oral medication can maximize safety, patient comfort, and mutual trust. Chemical restraint is needed when verbal warnings and voluntary acceptance of low-dose anxiolytics are not prudent options. Chemical restraint is preferred over physical restraint to control a violent patient, but these methods are often properly used together for rapid control of dangerous behavior. Physical restraint should be used for as brief a period as possible. Chemical restraint should be more broadly applied because sedation and anxiolysis are preferable.

Many patients with a history of chronic psychiatric conditions know, accurately, that they have the right to refuse antipsychotic medication in nonemergency settings. However, this right does not extend to patients who are acutely combative and in whom violent behavior threatens life or limb by failure to become calm through verbal or physical means. Although it is difficult to accurately predict the cause of agitation, the choice of chemical restraint agent should be tailored to the suspected cause of agitation, the optimal duration of sedation, and the depth of sedation needed.

Butyrophenones
Butyrophenones (haloperidol and droperidol) constitute the main class of typical antipsychotic medications recommended for an undifferentiated patient with acute agitation in the ED. The butyrophenones are considered high-potency antipsychotic agents because of their strong affinity for the dopamine D2 receptor in comparison with other typical antipsychotic agents. As a result of this affinity, the butyrophenones are more effective, cause less hypotension, and have fewer anticholinergic effects than older agents do.

Absolute contraindications to the use of butyrophenones include allergy to this class of drugs, anticholinergic drug intoxication, and a history of Parkinson disease. Relative contraindications include pregnancy, lactation, and hypovolemia. Butyrophenones are widely reported to decrease the seizure threshold, yet no conclusive evidence supports this observation, particularly in patients with sympathomimetic use.

The most common complications of the use of butyrophenones are related to extrapyramidal symptoms, which occur in less than 10% of patients within the first 24 hours of ED care. Dystonic reactions and akathisia are the most common manifestations of extrapyramidal symptoms requiring treatment in the ED. Akathisia is frequently misdiagnosed as psychiatric decompensation when it is manifested as restlessness, pacing, tension, and irritability. Extrapyramidal symptoms are treated with either benztpine (Cogentin), 2 mg, or diphenhydramine (Benadryl), 50 mg, intramuscularly or intravenously. Doses may be repeated every 5 minutes up to three times. Relief is rapid and dramatic in most cases. Benzodiazepines may be added for patients who do not respond initially. Many international providers use haloperidol in combination with promethazine because of its antihistamine and sedating properties. Studies show that this combination provides deeper sedation and requires less additional medication at 4 hours than an atypical antipsychotic does alone.

As with other neuroleptic agents, neuroleptic malignant syndrome has been reported with the use of butyrophenones (Table 195.1). This potentially fatal complex of autonomic instability is marked by high fever, muscle rigidity, and altered mental status. Aggressive symptomatic treatment includes cooling, benzodiazepines, dantrolene, and discontinuation of the offending agent.

HALOPERIDOL (HALDOL) Haloperidol may be given in 2.5- to 10-mg increments at 30- to 60-minute intervals for adults. Its onset of action is between 15 and 30 minutes and
its duration is 4 hours. Although a dosage ceiling has not been established, it is unusual to require more than three doses to achieve adequate sedation for an acute episode. It is rare to administer more than 60 mg in a 24-hour period.19

Though uncommon, the use of haloperidol in violent pediatric patients is well described. The pediatric dose of haloperidol is 0.075 mg/kg/day, repeated up to every hour (orally) or every 30 minutes (intramuscularly) at a dose of up to 2 mg/day in patients younger than 12 years. Of note, younger children are at greater risk for extrapyramidal symptoms than adolescents because of increased D2 receptor activity at younger ages.20,21

Although haloperidol is frequently given intravenously, this is an off-label use of the medication. Food and Drug Administration (FDA) approval is only for intramuscular or oral use. Prolongation of the QT interval has been observed with high-dose (e.g., 50 mg) intravenous haloperidol.

Haloperidol remains an effective and inexpensive option for the treatment of acute aggression. It is well tolerated if coadministered with an anticholinergic agent.20

**DROPERIDOL (INAPSINE)** Droperidol has a long history of use for the treatment of acute agitation in the ED. Studies have shown the superiority of droperidol over haloperidol within the first 30 minutes of intramuscular administration. The FDA issued a “black box” warning for droperidol in 2001, however, because of the risk for QT prolongation and ventricular dysrhythmias causing sudden cardiac death. Some authors analyzed the case records cited by the FDA and presented cogent arguments supporting continued use of this drug; these investigators questioned the reasoning behind the “black box” warning.22-24 Administration of droperidol for the treatment of violent patients and migraine headaches is now considered an off-label use of the drug. Droperidol is still approved for intravenous administration to prevent and treat postoperative nausea and vomiting.

Droperidol may be given in 2.5- to 5-mg increments intravenously at 15-minute intervals for adults. The intramuscular dose is 5 to 10 mg. Its onset of action is between 3 and 10 minutes. More than two doses are rarely required to achieve adequate sedation for an acute episode. The time to arousal is approximately 2 hours.19 Droperidol was found to produce more consistent moderate sedation than occurs with midazolam and the combination of droperidol and midazolam together.

Conduction abnormalities can develop with the administration of butyrophenones in high doses. The FDA “black box” warning for droperidol also referred to some cases of conduction abnormalities at low doses. Experts recommend obtaining an electrocardiogram before administering droperidol to patients in the ED, a recommendation that is impractical with an acutely agitated or violent patient. Although many authors disagree with the conclusions of the FDA, it is prudent to avoid the use of butyrophenones in elderly patients,

critically ill patients, or patients with known preexisting heart disease.18

Benzodiazepines
Benzodiazepines are preferred first-line agents for the acute management of agitation.12 Benzodiazepines are particularly useful for agitation caused by the ingestion of sympathomimetic agents and alcohol withdrawal. Sedation and mild respiratory depression are the most prominent side effects of benzodiazepines. Therefore, these drugs are quite safe in patients with most medical comorbid conditions. Lorazepam and midazolam are the two prototypic benzodiazepines used for the treatment of violent patients in the ED.

LORAZEPAM (ATIVAN) Observational studies have reported that lorazepam is at least as effective as haloperidol in treating patients with acute agitation. Lorazepam is given in 0.5- to 2-mg increments as frequently as every 15 minutes, depending on the patient’s level of sedation and respiratory status. Intramuscular injection is the most common route of administration and is quite reliable. Lorazepam has a shorter half-life than some parenteral benzodiazepines and lacks active metabolites. Lorazepam may also be given intravenously, orally, and sublingually. The time of onset after intravenous or intramuscular injection is between 15 and 30 minutes, and the drug’s effect lasts more than 3 hours. Sublingual or oral administration of lorazepam is a viable alternative route for patients who are cooperative and would benefit from rapid relief of anxiety (Table 195.2). Lorazepam is classified as a class D agent in pregnancy and thus should be avoided in pregnant and lactating women. Pediatric dosing of lorazepam is 0.05 mg/kg with doses of 0.5 to 2 mg orally or intramuscularly. Onset is 30 minutes orally and 15 minutes intramuscularly. The duration of effect is 6 hours orally or intramuscularly.20

MIDAZOLAM (VERSED) Midazolam is particularly beneficial if rapid sedation is required and prolonged sedation is less important. The first ED study describing midazolam for this indication used an intramuscular dose of 5 mg, which provided rapid sedation with a mean time to onset of 18 minutes and arousal at a mean time of 82 minutes.25 Another study reported the effective sedation time to be 45 minutes for midazolam and more than 2 hours for other agents.26 Fewer cardiorespiratory effects are seen with the intramuscular administration of midazolam; most authors have reported no difference in vital signs or oxygen saturation in comparison with other agents used to sedate agitated or violent patients when the 5-mg dose was administered.20,25 However, other authors have reported increased respiratory depression in patients suffering from alcohol intoxication.27 The intramuscular dose should be decreased by half in elderly patients or when midazolam is used in combination with opioid agents. Larger doses of midazolam (e.g., 10 to 15 mg intramuscularly) result in greater need for airway adjuncts.26

Treatment of oversedation and respiratory depression from the use of benzodiazepines in agitated or violent patients is supportive care (Fig. 195.3). Supplemental oxygen, repositioning, and airway adjuncts such as nasal trumpets suffice in most cases. Active airway management, including jaw thrusts, use of bag-valve-mask ventilation, or endotracheal intubation, is rarely necessary. It is prudent to avoid the use of flumazenil (Romazicon) because of the frequency of epileptogenic coingestion and the use of combination therapy with butyrophenones.

COMBINATION THERAPY The combination of lorazepam, 2 mg, and haloperidol, 5 mg, for sedation of agitated psychotic patients was found to be superior to either agent alone when investigators considered the speed of sedation and frequency of side effects. The duration of sedation was longer in patients receiving combination therapy.29 Lorazepam, haloperidol, and benztpine (Cogentin, 1 mg) can be administered in the same intramuscular syringe.

Atypical Antipsychotic Medications
Second-generation (atypical) antipsychotic drugs became feasible options for the treatment of agitated and violent patients in the ED with approval of the first intramuscular formulation in 2001. Several such medications are now available in intramuscular or rapidly absorbable formulations and are indicated for the treatment of acute agitation in selected patient populations. This class of antipsychotics acts by blocking both D2 and serotonin (5-HT) receptors and provides more tranquilization than sedation. The increased serotonin receptor activity results in fewer extrapyramidal effects. Second-generation antipsychotic agents are available in oral preparations, which allows easier conversion to long-term therapy when compared with the benzodiazepines and butyrophenones.

Atypical antipsychotic agents have been used in off-label fashion for the treatment of behavioral disorders in elderly patients for several years. In 2005, the FDA distributed an advisory describing a higher death rate in demented patients receiving atypical antipsychotic medications versus placebo. It is unclear how this advisory applies to the limited use of these drugs in the ED for acutely agitated elderly patients.

ZIPRASIDONE (GEODON) Ziprasidone is approved for the treatment of acute agitation in schizophrenic and bipolar/manic patients. Ziprasidone has not been extensively studied
Fig. 195.3  Respiratory depression after the administration of sedative medication (respiratory rate [RR] < 10 breaths per minute [bpm]). O₂, Oxygen; OP/NP, oropharyngeal/nasopharyngeal.

in patients with undifferentiated causes of agitation in the ED. The typical dose is 10 mg intramuscularly every 2 hours or 20 mg intramuscularly every 4 hours. Ziprasidone is associated with the greatest change in the QT interval of the atypical antipsychotics, comparable with the QT prolongation seen with haloperidol. In addition, ziprasidone needs to be diluted and is not as readily available for use as other agents.¹⁶ No dosing information is available for the use of ziprasidone in children with agitation, but the drug is used for the treatment of Tourette syndrome at a dose of 5 to 40 mg/day.²⁶

OLANZAPINE (ZYPREXA) Olanzapine is also approved for the treatment of acute agitation in schizophrenic and bipolar/manic patients in the ED. Olanzapine is available in either an intramuscular or oral disintegrating tablet formulation at 5 to 10 mg. Olanzapine is strongly sedating and demonstrates 160 times the antihistamine potency of diphenhydramine. Olanzapine causes the smallest change in QT interval of the atypical antipsychotics. Long-term use of the drug is associated with weight gain and hyperglycemia.²⁶ The manufacturer does not recommend the combination of intramuscular olanzapine with a parenteral benzodiazepine. Olanzapine has been approved for use in children at a dose of 0.1 mg/kg. Children younger than 12 years may receive 2.5 mg orally or intramuscularly. Children older than 12 years may be administered the adult dose. Its onset of action is 30 minutes orally and 10 to 20 minutes intramuscularly, with a duration of action of up to 24 hours.²⁰

RISPERIDONE (RISPERDAL) Risperidone is equivalent to haloperidol for the treatment of psychosis, and it is possibly more effective in treating aggressive behavior. Risperidone may be administered orally in the ED as a liquid formulation or as a rapidly disintegrating tablet at a dose of 1 to 3 mg. Although both methods of oral administration are easier with a cooperative patient, the liquid formulation can be mixed in a beverage or administered orally by syringe to resistant patients. The mean time until sleep was 43 minutes in one study. Risperidone has fewer anticholinergic properties, thus resulting in less confusion and sedation than with other atypical antipsychotic agents. Pediatric dosing of risperidone is 0.025 to 0.05 mg/kg. Children younger than 12 years may receive a dose of 0.25 to 0.5 mg orally. Pubertal pediatric patients may be administered a dose of 0.5 to 1 mg orally. Doses may be repeated two to four times until sedated. Its onset of action is 30 minutes with a peak concentration in 1 to 2 hours.²⁰

ARIPIPRAZOLE (ABILIFY) Aripiprazole is approved for the treatment of acute agitation in patients with schizophrenia and bipolar mania. It is available as a 9.75-mg intramuscular injection and may be repeated every 2 hours. Doses should not exceed more than 30 mg/day. Aripiprazole is equivalent to haloperidol with regard to control of agitation without oversedation.¹⁶ An oral dose of 2 mg is recommended for pediatric patients because of autism-related irritability or bipolar mania.

NEXT STEPS

Patients may demonstrate resolution of their agitation in the ED as a result of sleep or the metabolism of offending drugs and alcohol. Patients may be considered for discharge if they have normal mental status without agitation on waking, as long as other acute medical and psychiatric conditions have been addressed. Patients who continue to exhibit violent or threatening behavior, abnormal vital signs, or evidence of psychiatric decompensation require further medical or psychiatric care.
Agitated or violent patients who elope from the ED before full evaluation or resolution of their symptoms represent a significant legal risk to providers, as well as a risk to the safety of themselves and other individuals. Legal authorities should be notified of the elopement of such patients.

Self-Harm and Danger to Others

Nicole Malouf, Benjamin F. Jackson, and Keith Borg

KEY POINTS

- Risk factors that increase the likelihood of self-harm include depression and other mental disorders, alcohol or substance abuse, separation or divorce, physical or sexual abuse, and significant medical conditions such as human immunodeficiency virus infection, cancer, and dialysis-dependent renal failure.
- Psychiatric illness and substance abuse increase the likelihood of homicidal ideation.
- Although adolescent and young adult female patients are more likely to be treated in the emergency department after a suicidal gesture, older men are more likely to commit suicide.
- In the United States, all 50 states provide physicians the legal right to commit any patient who is a threat to either self or others.
- Health professionals are required to inform individuals directly if they are at risk for harm from a homicidal patient. Police should also be notified of such risk.
- Any patient discharged from the emergency department after appropriate psychiatric evaluation should agree to immediately seek medical care if thoughts of violence or self-harm return.

EPIDEMIOLOGY

Patients with suicidal or homicidal ideation are encountered frequently in the emergency department (ED). Approximately 0.4% of all ED visits in the United States involve suicidal patients, and suicide accounted for 34,598 deaths in 2007 (almost twice the number of deaths by homicide, 18,361), which makes it the 10th leading cause of death overall.1 For Americans aged 15 to 24 years, suicide ranks as the third leading cause of death.2 This age group also accounts for more ED visits for attempted suicide and self-injury than any other age group does. More than 1200 children and adolescents complete suicide annually in the United States,3 and it is estimated that 11 attempted suicides occur per suicide death.4 More than 40% of individuals 16 years or older who completed suicide were evaluated in an ED in the year before their terminal act.5

Although the rate of attempted suicide was highest in female patients 15 to 19 years old, nearly five times as many males died by suicide in this age group. About six times as many males as females died by suicide in the 20- to 24-year age group, and older, non-Hispanic white men have a suicide rate than is staggeringly higher than the national average for the general population. Of patients with evidence of self-harm, poisoning was the cause of death in 13% of males and 40% of females, suffocation in 24% of males and 21% of females, and firearms in 56% of males and 30% of females.1 Self-mutilation (by cutting or piercing) was observed in 20% of patients evaluated in the ED for a suicidal gesture. One third of suicidal patients were admitted for inpatient management, one third were transferred to an off-site facility, and one fifth were referred to outpatient psychiatric services.6

Intentionally harmful behavior also constitutes a growing problem in children, adolescents, and young adults. It has been estimated that the prevalence of mental illness among youth in Canada and the United States approaches 15% to 20%, with an anticipated 50% increase by 2020. Pediatric mental health complaints account for 1.6% of all annual ED visits in the United States and 1% of all annual ED visits in Canada.7,8

Homicide ranks as the most common cause of death in black males 15 to 24 years of age and is the second leading cause of deaths for all youths in this age group. In 2005 alone, more than 5000 deaths by homicide occurred in this age group, and in 2006 this age group received medical care for more than 750,000 cases of nonfatal violent injury.6

A focused risk assessment is the primary objective for the emergency provider caring for a patient who is threatening harm to self or others. Risk assessments vary widely, depending on the circumstances of the patient, comorbid disease, mental status, and other social issues. The main challenge to effective risk assessment is the lack of a specific diagnostic test to stratify threat in suicidal or homicidal patients. No interventional test is currently available to determine who is at greatest risk for injury—data for risk stratification come from psychologic autopsy, which is the study of patient characteristics in completed suicides. Predictive data for outcomes of these patients after ED evaluation are lacking. This chapter focuses on the directed examination and evaluation of patients who pose threats of harm to self or others.

PATHOPHYSIOLOGY

Numerous factors influence the likelihood of self-harm, including depression and other mental disorders, alcohol or substance abuse, separation or divorce, physical or sexual abuse, and significant medical conditions such as human...
immunodeficiency virus infection, cancer, and dialysis-dependent renal failure (see the “Red Flags” box). Previous suicide attempters also have more concurrent general medical conditions, alcohol or substance abuse, work hours missed, and current suicidal ideation than do nonattempters. More than 90% of people who die by suicide have a mental health disorder, a substance abuse disorder, or both. Depression is a significant and common risk factor to address because one in three patients encountered in the ED have moderate to severe depression. In adult male ED patients, depression is more strongly associated with the likelihood of perpetrating violent behavior than excessive alcohol consumption is.  

Besides the presence of risk factors, poorly understood biologic factors probably influence self-harm. Serotonin levels have been studied in suicidal patients, and data suggest that lower levels of cerebral 5-hydroxyindoleacetic acid (a serotonin metabolite) are found in patients who attempt suicide. Increasing serotonin levels through pharmacotherapy with drug classes such as tricyclic antidepressants or selective serotonin reuptake inhibitors is a common treatment of depression and suicidal ideation.

**PRESENTING SIGNS AND SYMPTOMS**

Patients may seek treatment in the ED after considering or attempting to harm themselves or others. These actions range from unsuccessful, yet serious gestures to the use of suicidal ideation for secondary gain. Clinical suspicion should always be high, and patients’ complaints must be taken seriously. Careful, open-ended, nonjudgmental questioning can help discern the level of risk by understanding the patient’s intent.

In addition, emergency physicians should be cognizant of interactions with adolescent patients and consider screening either formally or informally for suicidal ideation. A recent study evaluated the feasibility of screening nonpsychiatric patients for suicide risk and targeted patients between the ages of 10 and 21 years. In this study interval, 37 of 50 patients with psychiatric complaints screened positive for suicide risk. However, 27 of 106 patients evaluated for nonpsychiatric complaints also screened positive for suicide risk. Each of the patients underwent formal psychiatric consultation, and none of the patients with nonpsychiatric complaints warranted hospitalization but were provided with available outpatient psychiatric services. Interestingly, screening of nonpsychiatric patients did not increase the overall length of stay.

Injured patients with a concerning mechanism (ingestion, single-person car accident, fall) should be screened for suicidal ideation and intent. If an attempt is uncovered, the provider should solicit the patient’s feelings about survival. It is important to understand why patients survived as a predictor of immediate or ongoing risk for harm. The following questions should be considered:

Was the patient found accidentally?
Did a low-risk gesture precede a phone call for help?
Is the patient sad to have survived?
Is the patient having increasing thoughts of suicide?
Does the patient have a plan? Has the patient gathered the means to act on that plan?

Is the patient feeling depressed or hopeless, or does the patient appear withdrawn?
What are the patient’s risk factors for future suicidal ideation or attempts?

A practice guideline of the American Psychiatric Association summarized large amounts of retrospective data regarding risk factors in patients who committed suicide. The relative importance and clinical utility of such risk factors can be challenging, however. Seemingly innocuous patient data may represent significant risk, as evidenced by studies demonstrating a higher suicide rate in women who received breast implants. Such epidemiologic studies are difficult to translate into clinical practice, but they do provide an understanding of the complexity of risk stratification in suicidal and homicidal patients.
Differential Diagnosis and Medical Decision Making

The differential diagnosis of self-harm includes minor depression, major depression, suicidal ideation, suicidal gestures, and suicidal attempts of varying lethality and intent. Other alternative diagnoses can be difficult to establish in the ED. One such alternative is the threat of suicide for secondary gain; very little is written or researched about patients with such intents. The goal of secondary gain is often hospitalization to avoid incarceration, legal prosecution, homelessness, or other social problems. A second alternative diagnosis is intentional self-mutilation, such as cutting or hair pulling. This is differentiated from suicidal ideation by its nonlethal intent and frequency of the behavior. Self-mutilation is believed to be a maladaptive response to stress.

Most Common and Most Threatening Presentations

Common manifestations of suicidality include minor threats or ideation of suicide by nonlethal means (Box 196.1). The most frequent ED scenarios involve young female patients who report a recent ingestion. Depressive symptoms are also common.

Men are far more likely to complete suicide. Threatening scenarios include attempts with potentially lethal consequences, a history of previous attempts, traumatic attempts that are difficult to recognize (e.g., single-car motor vehicle crashes), and elderly men with suicidal ideation.

Diagnostic Testing

Diagnostic testing in patients with threats of harm to self should focus on the mechanism of the suicidal attempt and any significant comorbid disease (including alcohol and drug abuse). Specific testing may help in evaluating certain treatable ingestions, such as acetaminophen or salicylates; in many cases, however, no specific testing is required. Imaging should be ordered appropriately for patients whose harmful actions involve jumping, hanging, or other traumatic injuries. Screening laboratory tests may be required to arrange for transfer or admission to a psychiatric facility, although such testing has little diagnostic value in the ED evaluation and treatment of suicidal or homicidal patients.14

Priority Actions

Evaluate for any immediate life threats from a suicide attempt or current ideation.
Place the patient in a setting in which constant monitoring is possible.
Minimize the patient’s risk to self, staff, and others.

Treatment

Patients who have attempted suicide must be evaluated immediately to determine the lethality of the reported or suspected method of harm. Once the threat assessment is complete, the patient should be placed in a closely monitored setting. Physical or chemical restraint and suicide precautions may be required in certain circumstances. Suicide precautions include undressing and gowning the patient, removal of potential weapons or harmful items, one-on-one or video supervision, and security escort for travel and transfer. Careful questioning and examination of the patient should establish the level of risk and cooperation.

All 50 states provide the physician the ability to commit any individual who is a threat either to self or to others or who is unable to care for himself or herself. This psychiatric hold is time limited (usually 72 hours) to permit emergency evaluation and treatment of the patient. The specific actions and documentation required to commit a patient vary by state jurisdiction. Adherence to the process is very important, and the decision to act should be made with appropriate gravity. Documentation of the reason for committal should be provided in clear detail, and supplementary historical information from family, police, or others should also be included in the chart.

Terasoff v. Regents of the University of California was a landmark legal decision in 1976 that established an obligation by the health care professional to warn a specific individual if there is identifiable risk for harm, thus overriding the patient’s confidentiality. To fulfill this obligation, both the threatened individual and the police must be informed of the intentions of the homicidal patient. Patients who have an intention to hurt or kill an identifiable individual should be committed and evaluated by a psychiatrist. Discussions with legal and psychiatric colleagues should clarify who will perform any required notification.

Contracts for safety are pacts that include a patient’s promise to seek immediate evaluation should thoughts of violence or self-harm increase. Current American Psychiatric Association guidelines do not recommend contracts for safety in emergency situations, although such understandings should be reinforced with any patient who is discharged after psychiatric evaluation in the ED.

Disposition

Once the initial challenges of medical assessment have been met, the practitioner should determine the safest and...
most appropriate disposition for the individual patient’s social condition (Fig. 196.1). Psychiatric consultants often aid in the necessary evaluation, admission, or follow-up of at-risk patients. If the clinician has significant concerns, the patient should be admitted or transferred to an appropriately safe inpatient setting. Patients may need to be committed for involuntary psychiatric admission if they are not willing to sign in voluntarily.

One prospectively validated tool that is valuable for use in the ED is the Modified SAD PERSONS Scale developed by Hockberger and Rothstein in 1988 (Table 196.1). The scale uses a series of criteria that allow easy review of risk factors and assist in the identification of conditions that should

*The score equals the points for all 10 parameters: minimum score, 0; maximum score, 14. The higher the score, the greater the risk for suicide. A patient with a score of 5 or less rarely requires hospitalization.
prompt admission. Patients with a low score are less likely to have adverse events.\(^\text{1}\) However, patients testing positive for anxiety and hopelessness with concurrent depression are at increased risk to commit suicide.\(^\text{7}\)

As evidence suggests from multiple studies, the following four items have also demonstrated high sensitivity and specificity for predicting suicidality in adolescents:

Are you here because you tried to hurt yourself?
In the past week, have you been having thoughts about hurting yourself?
Have you tried to hurt yourself in the past other than this time?
Has something very stressful happened to you in the past few weeks?\(^\text{9,16,17}\)

For homicidal patients or victims of violent injury, it is incumbent on the provider to assess the risk for retaliatory violence. Because retaliation often occurs in the weeks immediately following an incident and commonly involves firearms, the following screening questions (known as the “FiGHTS” mnemonic) may aid the ED clinician in determining an adolescent’s risk for carrying handguns:

Fights: During the last 12 months, have you been in a physical fight?
Gender: Male
Hurt: During the last 12 months, have you been in a fight in which you were injured and had to be treated by a physician or nurse?
Threatened: During the last 12 months, have you been threatened with a weapon (knife or gun) on school property?
Smoker: Have you ever smoked cigarettes regularly (1 cigarette per day for 30 days)?\(^\text{9}\)

A positive screen for suicidal or homicidal ideation or intent should prompt further evaluation and management, but patients may be discharged home if they are deemed safe after medical evaluation and psychiatric consultation (Box 196.2). Among patients discharged from the ED, significant predictors of return visits within 30 days include lack of a caregiver at the time of discharge and a history of a previous suicide attempt.\(^\text{18}\) A treatment plan, return precautions, and conditions for safety should be clear, well documented, and understood by all parties involved (including friends, family, and caregivers of the patient, especially when children or adolescents are involved).

**Box 196.2 Reassuring Factors for Safe Discharge**

- Care established for mental, physical, and substance abuse disorders
- Follow-up in 1 to 2 days
- Family and community support
- Problem-solving and conflict resolution skills
- Cultural and religious beliefs that discourage suicide and support the patient

REFERENCES

Anxiety disorders are the most common psychiatric illnesses diagnosed in children, adolescents, and older adults. Anxiety disorders may significantly affect a patient’s quality of life and overall health. Anxiety is commonly associated with depression, other mood disorders, and substance abuse.

Numerous potentially life-threatening medical disorders feature symptoms that often mimic anxiety on initial evaluation. Emergency physicians must be able to discern such serious medical conditions from a principally anxious patient.

**PATHOPHYSIOLOGY**

Anxiety disorders are caused by a combination of biologic factors and environmental influences. Despite increased basic science and clinical research, a specific explanatory mechanism or model to describe the exact causes of anxiety has yet to be identified.

The genetic epidemiology of anxiety disorders has been confirmed by numerous studies and metaanalysis. Most anxiety disorders have significant familial aggregation, with the inheritability of panic disorder approaching a rate of 40%.

Several neurotransmitters play integral roles in the pathophysiology of stress and mood and anxiety disorders. Decreased γ-aminobutyric acid and serotonin receptor sensitivity are common in most anxiety disorders. Overactivity of the central norepinephrine system and elevated sensitivity to lactate and carbon dioxide are prominent findings in panic disorder. Cholecystokinin and increased excitatory neurotransmission by glutamate may contribute to the evolution of conditioned fear.

An environmental factor is integral to the development of anxiety. Stressful childhood experiences, such as abuse and divorce, contribute to generalized anxiety and panic disorders. Caffeine and other socially accepted stimulants (e.g., taurine, ginseng), as well as recreational substances (e.g., cocaine, methamphetamine, γ-hydroxybutyrate, jimson weed, salvia), often promote symptoms of anxiety. Finally, increasing exposure to violence, natural disasters, terrorism, and other traumatic events has caused greater numbers of people to suffer from acute stress reactions, anxiety, depression, and posttraumatic stress disorder.
Anxiety may be accompanied by many somatic and cognitive signs and symptoms, as listed in **Box 197.1**. The physical symptoms of acute anxiety are similar to those of excitation, such as chest pain, dry mouth, dyspnea, lightheadedness, and palpitations. Symptoms of subacute or chronic anxiety include fatigue, insomnia, and menstrual abnormalities. An anxious patient may have normal findings on physical examination or may exhibit tachycardia, tachypnea, and diaphoresis.

Psychologic symptoms of anxiety include distractibility, emotional lability, noncompliance, and recurrent or obsessive thoughts. An anxious patient may be easily startled, demonstrate pressured speech, or suffer repetitive behavior.

Children may not be able to articulate their fear or anxiety. As a result, an anxious pediatric patient may have seemingly disparate chief complaints, such as nonspecific abdominal pain and headache. During examination, anxious pediatric patients may have a temper tantrum or may appear more clingy or needy than expected.

A panic attack may be the feature of most anxiety disorders. A panic attack is a discrete episode of intense fear or discomfort in the absence of real danger that meets specific symptomatic criteria. The intensity of a panic attack usually peaks within 10 minutes and resolves within 30 minutes. Panic attacks are often accompanied by at least 4 of 13 discrete somatic and cognitive symptoms.

### Differential Diagnosis, Diagnostic Criteria, and Testing

As evidenced by the broad range of associated signs and symptoms, anxiety disorders are part of an extensive differential diagnosis. Anxiety may represent a primary psychiatric condition or may be secondary to a medical illness. More than a dozen different anxiety disorders have similar physical symptoms and signs (Box 197.2).

The first and most important step in evaluating an anxious patient is to search for potential medical causes of the patient’s symptoms. As noted in **Table 197.1**, many different medical conditions and medications mimic, manifest, produce, or exacerbate anxiety. Thorough evaluation of all of the patient’s recent and past medical problems, current medications and supplements (including those available over the counter), family history, and social history (especially substance use and social stressors) may preclude an exhaustive and unnecessary medical work-up. The onset of a new behavioral symptom at a late age or the report of any feature that is not typically associated with anxiety increases the likelihood of a medical cause.

An appropriate physical examination helps identify or eliminate potential causes of anxiety. Abnormal vital signs and characteristic toxidromes often signal the presence of a medical illness or drug-associated condition. A focused neurologic examination, including mental status, is critical to the diagnosis of intracranial disease.

Myocardial infarction, angina pectoris, and dysrhythmias may have clinical findings similar to those of a panic attack. Several studies have indicated that up to 30% of patients with chest pain who are evaluated in the ED meet the diagnostic criteria for panic disorder. Alternatively, more than 40% of patients with panic disorder had documented coronary artery disease in a related study.

Nearly 25% of medical conditions that cause symptoms of anxiety are endocrine disorders such as hypoglycemia, hyperthyroidism, and hypoparathyroidism. Approximately 30% to 50% of female hyperthyroid patients suffer from panic and generalized anxiety disorders.

Transient ischemic attacks, temporal lobe seizures, and brain tumors may promote anxiety. Up to 50% of patients with intracranial tumors, such as pituitary adenomas and metastatic disease, may have psychiatric manifestations.

Exacerbations of asthma and chronic obstructive pulmonary disease may mimic the hyperventilation and respiratory distress observed during a panic attack. A patient with acute pulmonary embolism may exhibit chest tightness, dyspnea, diaphoresis, and apprehension.

An appropriate screening evaluation with laboratory and ancillary tests should be considered for anxious patients whose findings are not consistent with a past episode. At minimum, a chemistry panel, complete blood count, pregnancy test, prescription drug levels, and toxicology screen are often necessary. If indicated, additional tests such as an electrocardiogram, computed tomography of the brain, thyroid levels, or lumbar puncture may also be obtained.

### Treatment

Treatment of an anxious patient should begin with the creation of a calm, quiet clinical environment. An empathetic tone and willingness to listen will relieve some of the patient’s anxiety.
**BOX 197.2 Definitions of Anxiety Disorders**

**Panic attack** is a discrete period characterized by the sudden onset of intense apprehension, fearfulness, or terror; it is often associated with feelings of impending doom.

**Agoraphobia** is anxiety about or avoidance of places or situations from which escape may be difficult (or embarrassing) or in which help may not be available in the event of a panic attack or panic-like symptoms.

**Panic disorder without agoraphobia** is characterized by recurrent, unexpected panic attacks about which persistent concern exists.

**Panic disorder with agoraphobia** is characterized by both recurrent, unexpected panic attacks and agoraphobia.

**Agoraphobia without history of panic disorder** is characterized by the presence of agoraphobia and panic-like symptoms without a history of unexpected panic attacks.

**Specific phobia** is characterized by clinically significant anxiety provoked by exposure to a specific fear, object, or situation; it often leads to avoidance behavior.

**Social phobia** is characterized by clinically significant anxiety produced by exposure to certain types of social or performance situations; it often leads to avoidance behavior.

**Obsessive-compulsive disorder** is characterized by obsessions (which cause marked anxiety or distress) or compulsions (which serve to neutralize anxiety).

**Posttraumatic stress disorder** is characterized by the recurrent mental experience of an extremely traumatic event accompanied by symptoms of increased arousal and avoidance of stimuli associated with the trauma.

**Acute stress disorder** is characterized by symptoms similar to those of posttraumatic stress disorder that occur immediately after an extremely traumatic event.

**Generalized anxiety disorder** is characterized by at least 6 months of persistent and excessive anxiety and worry.

**Anxiety disorder due to a general medical condition** is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of a general medical condition.

**Substance-induced anxiety disorder** is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of drug abuse, medication use, or toxin exposure.

**Anxiety disorder not otherwise specified** is included for coding disorders with prominent anxiety or phobic avoidance that do not meet the criteria for any of the specific anxiety disorders.

as well as facilitate an appropriate medical evaluation. The presence of a trusted, supportive friend or family member may also be helpful.

Benzodiazepines are the recommended first-line agents for pharmacologic management and may be given orally to patients in the ED for minimal to moderate symptoms. In those with severe symptoms, intravenous lorazepam, diazepam, and midazolam should be administered. Lorazepam may be given in 0.5-mg doses, whereas diazepam and midazolam may be given in 1- to 2-mg increments. For milder, less urgent symptoms and limited outpatient use, the recommended dose of clonazepam and alprazolam is 0.25 to 0.50 mg. Buspirone, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, and recently, cognitive behavioral therapy are used by psychiatrists for the outpatient treatment of anxiety disorders.

DISPOSITION

Most anxious patients may be discharged home after appropriate ED evaluation and stabilization. Immediate psychiatric consultation is recommended for anxious patients who report suicidal or homicidal ideation, who are severely depressed or unable to care for themselves, or who may not have reliable follow-up. Coordination with a behavioral health resource or case management–based intervention may also improve follow-up care. Anxious patients discharged from the ED should be instructed to seek care from their primary physician or mental health provider as soon as possible.

Conversion Disorder, Psychosomatic Illness, and Malingering

Glen E. Michael and J. Stephen Huff

Somatization disorder, conversion disorder, and hypochondriasis are psychologic reactions to stressful circumstances that are neither intentional nor planned. Malingering and factitious disorders involve deliberate actions of deceit of which the patient is aware. Somatoform conditions feature complaints and symptoms that cannot be attributed to medical illness. Emergency department evaluation of patients with suspected somatoform disorders should focus on the search for a medical cause of the reported symptoms and exclusion of life-threatening illness. Identification and appropriate referral of patients with somatoform illness are secondary objectives of the emergency department encounter. As with other psychiatric and medical diagnoses, thorough documentation is required when somatization is suspected.

Somatoform conditions include the following diagnoses: somatization disorder, conversion disorder, somatoform pain disorder, hypochondriasis, body dysmorphic disorder, and undifferentiated somatoform illness. The boundaries between these disorders can be subtle, and it has recently been proposed that four of these conditions—somatization disorder, somatoform pain disorder, hypochondriasis, and undifferentiated somatoform illness—should be reclassified under a single common rubric called complex somatic symptom disorder (CSSD). Further classification of somatoform disorders is continually evolving as research better defines their distinctive characteristics.

The reported prevalence of somatoform conditions ranges from 50% to 65% in ambulatory settings. When definitions are narrowed to include only patients meeting strict diagnostic criteria for somatization disorder, the lifetime prevalence drops to less than 3%. Accurate classification is difficult because some patients exhibit somatoform symptoms in the presence of demonstrable medical illness.

True somatization disorder (or Briquet syndrome, after Paul Briquet, who first described the illness in 1859) is typically manifested before 30 years of age and is far more common in women than in men. Although many patients somatize, somatization disorder is ultimately diagnosed in few.

DEFINITIONS

Somatization disorder is characterized by the presence of multiple chronic distressing somatic symptoms that are not medically explained. Patients with this condition tend to be highly anxious about their symptoms, even in the face of evidence that their condition is not medically serious. In the draft of the upcoming Diagnostic and Statistical Manual of Mental Disorders (DSM-V), this condition has been renamed CSSD.

Hypochondriasis is preoccupation with or excessive fear of illness despite negative testing and reassurance from a healthcare professional. Hypochondriasis is more common than somatization disorder and has a prevalence of 4% to 9% in general medical practice. It peaks in men in the fourth decade and in women in the fifth, with no significant predilection by gender. Hypochondriasis is increasingly being described in geriatric populations. It has been renamed the “predominant health anxiety” subtype of CSSD in the proposed draft of DSM-V.

Somatoform pain disorder, an important and particularly challenging somatoform illness, is characterized by somatoform symptoms that are manifested predominantly as pain. In the proposed draft of DSM-V, this condition is reclassified as the “predominant pain” subtype of CSSD.

Conversion disorder is a condition in which patients complain of sensory or motor symptoms as a manifestation of stress or unconscious conflict that cannot be attributed to a pathophysiologic process. Conversion disorder is more common in women and members of lower socioeconomic groups. Its onset typically begins in adolescence, and it follows a discontinuous course. Conversion disorder has also been observed in military, mass casualty, and industrial accident settings without a female preponderance of the disorder. Estimates of prevalence vary considerably as a result of inconsistent classifications and definitions of the disorder.
**Body dysmorphic disorder** is characterized by a preoccupation with an imagined defect in physical appearance. Although it is currently classified under somatoform disorders, body dysmorphic disorder more closely resembles obsessive-compulsive disorder and as a result may be moved to the anxiety disorders section of the DSM-V. This disorder is commonly encountered by primary care providers, plastic surgeons, and the body enhancement industry.

**Factitious disorders,** including malingering, feature deliberate manufacturing of symptoms or illness. The combined prevalence of all factitious disorders ranges from 1% to 5%, again with a female preponderance. The term Munchausen syndrome (after the famous 18th-century raconteur Baron von Munchhausen) is reserved for chronic or “career” medical imposters, and it represents the extreme form of the disorder. However, cases of Munchausen syndrome tend to involve male patients.

Malingering and symptom exaggeration are probably underreported. In one study, “39% of mild head injury, 35% of fibromyalgia/chronic fatigue, 31% of chronic pain, 27% of neurotoxic, and 22% of electrical injury claims resulted in diagnostic impressions of probable malingering” Malinger- ing is most often exhibited by patients who are either trying to avoid an unpleasant circumstance, such as military duty or a prison term, or attempting to secure some form of compensation, such as occupational health or personal injury plaintiff claims. Malingering can result in criminal charges.

**Factitious disorder by proxy or Munchausen syndrome by proxy** deserves special mention because it may represent a form of child abuse. It is typically defined as the intentional production or feigning of physical or psychiatric illness in a child by the child’s guardian, although it has also been reported in caregivers of geriatric patients. Factitious disorder by proxy can be active (symptom producing) or passive (neglect). Munchausen syndrome by proxy is rare and occurs in roughly 2.8 per 100,000 children younger than 1 year and 0.5 per 100,000 children younger than 16 years. As with the other factitious illnesses, the deceptive nature of the disorder makes it extremely difficult to detect and study.

**PATHOPHYSIOLOGY**

Somatoform illnesses represent emotional stress experienced as physical symptoms. Both somatization and hypochondriasis are commonly associated with depression and anxiety, and somatization is classified as a potential initial symptom of depression. This strong association with depressive disorders has led to the practice of treating somatization with antidepressant medications. Hypochondriasis and depression coexist in roughly 40% of cases. Twenty percent of patients with hypochondriasis have a diagnosis of panic disorder, and 10% have an obsessive-compulsive disorder. As the number of reported physical symptoms rises in patients with somatoform illness, the likelihood of an underlying psychiatric disorder increases proportionately.

A significant correlation does not appear to exist between psychiatric illness and factitious disorder, unlike somatization and hypochondriasis. Malingering is observed in individuals with antisocial and psychopathic personalities, but the nature of this association remains unclear.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC FEATURES**

**Somatization** is exhibited by patients who are chronically and persistently “sick” with numerous vague complaints and symptoms involving many organ systems; review of systems is often globally “positive.” Patients’ symptoms are distressing to them, and their suffering is authentic even if medically inexplicable. Patients maintain a very strong conviction of illness despite multiple negative diagnostic work-ups, hospital admissions, specialist referrals, and surgical procedures. An example of the breadth of symptoms associated with somatoform disorders can be seen in the diagnostic criteria listed in Box 198.1.

Patients with hypochondriasis, like somatizers, are convinced that they are gravely ill. Although a somatizer focuses on symptoms, a patient with hypochondriasis focuses on disease states and invests great personal energy in seeking multiple extensive reassurances from the health care system. Patients with hypochondriasis are typified by health anxiety leading to strong convictions of illness and fixation with the body and its functions. Ominous implications are often attributed to mundane or insignificant findings, and symptoms are exaggerated out of proportion to any actual organic illness.

**Conversion disorder,** in contrast to somatization disorder, is the acute, often episodic onset of one symptom or sign involving limited body parts or organ systems. Complaints are generally sensory or motor in nature and often occur in response to an identified stressor. Unlike malingering or factitious disorders, the malady is not consciously feigned or deliberate. Examples of conversion disorder typically seen in the ED include pseudoseizures, altered mental status, paralysis, and movement disorders. Other common conversion symptoms are presented in Box 198.2.

**BOX 198.1 Diagnostic and Statistical Manual of Mental Disorders (Fourth Edition, Text Revision) Criteria for Somatization Disorder**

1. Pain in at least four distinct locations or circumstances (e.g., headache, backache, chest pain, dysuria, dyspareunia)
2. Two or more gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea, constipation, but not pain)
3. One or more sexual dysfunction symptoms (e.g., impotence, lack of libido, menorrhagia, but not pain)
4. One or more neurologic conversion symptoms (also see Box 198.2) (e.g., paresthesia, paralysis, ataxia, blindness, pseudoseizure)

Symptoms are not medically explainable or may represent an exaggeration of symptoms attributable to an organic illness. Symptoms must not be deliberately produced.

One of the more unusual conversion disorders is pseudocyesis, or “hysterical pregnancy,” which includes the physical symptoms of pregnancy (even amenorrhea) in the absence of a true gestation.

La belle indifférence, a seemingly incongruous disinterest in one’s illness, is classically associated with conversion reactions. However, la belle indifférence may be seen with organic disease states such as stroke. La belle indifférence should not be used alone to differentiate between conversion and organic disorders.15

Patients who malingre and those who have factitious disorder tend to limit themselves to exaggerations of symptoms of a previously diagnosed illness or to symptoms that are difficult to investigate and disprove; examples include pain of any variety, psychiatric conditions such as suicidality, and the pseudoneurologic symptoms of tingling, amnesia, and seizures. Less commonly, patients with factitious disorder inflict injury or disease on themselves. Deliberate misuse of medications such as hypoglycemic agents has been described in health care workers.10

Unlike the somatoform disorders, malingering and factitious behavior involve feigned illness. Even though they are aware of their deception, patients with factitious disorder (unlike malingerers) are helpless to control the behavior.19 To illustrate the differences among somatoform disorder, factitious disorder, and malingering, one can use the example of nonepileptic or pseudoseizures, which can be seen in each condition. A patient with a somatoform disorder suffers a nonvolitional convulsion in response to a psychologic stressor, a patient with factitious disorder has an uncontrollable compulsion to feign a nonepileptic convulsion to gain attention and the sick role, and a patient who malingers feigns a convulsion as part of a ruse to achieve a specific end. What sets malingering apart from factitious disorder is the patient’s intentional pursuit of an identifiable, tangible goal or gain.20

**VICTIMS OF INTIMATE PARTNER VIOLENCE**

Among patients who tend to use emergency care frequently, an important subgroup consists of victims of intimate partner violence (see Chapter 93). Intimate partner violence results in high levels of psychologic stress for the victim. Many of these patients repeatedly seek care in the ED with somatoform behavior.21 Physicians must screen for ongoing abuse when new or recurrent physical symptoms cannot be attributed to a medical condition. Just as with current abuse, patients with a past history of physical, sexual, or psychologic abuse also tend to use medical services more frequently.

**DIFFERENTIAL DIAGNOSIS AND TESTING**

In the emergency department (ED), the brevity of the clinical encounter and a diagnostic focus on life threats make accurate identification of patients with somatoform disorders difficult. Even when demonstrable medical disease is present, symptoms and severity are modulated by the psychologic well-being of the patient. Even though it stands to reason that many patients somatize to some degree, clearly a subset exists in whom such behavior represents a disorder.

The goals when evaluating somatoform illness are identification of the condition and appropriate referral. In the ED, life-threatening conditions on the differential diagnosis are excluded first, other potentially serious medical illnesses are excluded second, and somatoform causes are excluded last, if at all.

Classic findings can make one suspect a somatoform illness; however, such behavior is insufficient for psychiatric diagnostic criteria. Synopses of the characteristics of somatoform disorders can be found in Table 198.1. It is useful to categorize these illnesses as nondeliberate (somatization,
Conversion disorder, and hypochondriasis) and deliberate (factitious disorders and malingering).

The symptoms experienced by a patient with a nondeliberate somatoform illness are perceived as very real. Diligent history taking often uncovers telling patterns. Useful questions to consider include the following: Are these complaints chronic? Do they correlate with identifiable stressors? Does the patient hold a conviction of a particular illness or imminent death? Does the patient have a lifelong history of “illness”? What has been done for this patient in previous visits, by previous providers? What is new today? Obtaining answers to these questions, along with a careful physical examination, can help direct the emergency evaluation while at the same time reassuring patients that they are being taken seriously. Respect ultimately aids in disposition because these patients are far more likely to comply with a plan when they believe that a provider has their best interests at heart.

Concerns about making the diagnosis of a somatoform illness should not preclude a thorough ED evaluation because many medical conditions can be mistaken for somatization, particularly when the findings are atypical. Box 198.3 provides examples of medical conditions that can mimic somatoform behavior.

As a general rule, patients with nondeliberate somatoform illness acquiesce to invasive diagnostic testing, whereas those with factitious disorders and malingerers are more reluctant. The presence of two or more of the following features is suggestive of malingering behavior: mention of a medicolegal context of the visit, discrepancy between subjective and objective assessment of the degree of stress and disability, poor compliance with evaluation and treatment, and antisocial personality disorder. Malingering is very difficult to prove, even in the presence of high clinical suspicion and deliberate investigation, and surveillance of the patient is often required. Determination of malingering is usually the purview of specialists such as neuropsychologists.

Various maneuvers are purported to assist in identifying factitious symptoms, as shown in Table 198.2. Waddell’s “behavioral responses to examination,” as applied to a chief complaint of back pain, are one example. Although the Waddell signs provide a compelling method of detecting feigned illness, the predictive value of such maneuvers is generally poor and correlates with an unfavorable treatment outcome.

Tests for factitious paralysis have also been proposed but are similarly nonspecific. The abductor test is one such test: with true paresis, the unaffected leg abducts when the patient attempts to abduct the affected leg against resistance. The Hoover test involves placing the examiner’s hand under the “weakened” lower extremity and asking the supine patient to raise the unaffected leg; downward pressure with the affected leg is considered positive for feigned paralysis. Prudent caution is warranted in the interpretation of any diagnostic maneuver that is infrequently performed.

**TREATMENT**

No specific treatment of nondeliberate somatoform illness exists. Psychiatric comorbid conditions such as depression, anxiety, and substance abuse should be addressed. Cognitive behavioral therapy has shown promise in the minority of patients willing to be referred.

Whether to use medication to treat symptoms believed to be somatoform in origin is as much an ethical question as a medical one. This quandary often develops when considering analgesics for chronic pain syndromes. In accordance with the principles of beneficence and nonmaleficence, one may want to spare a patient potential side effects and addiction; this is

countered by the harm of leaving a patient in pain or consigning
the patient to withdrawal if he or she is a chronic user of
analgesics.

The final common pathway of pain is the perception of
pain, and even imagined pain can be very real. Given that
emergency providers do not primarily manage somatoform
illness, it is not unreasonable to provide short-term “bridging”
prescriptions on a case-by-case basis to patients with appro-
priate follow-up arrangements. Patients who seek care only
to acquire narcotics are not considered to be suffering from
somatoform illness; rather, they may have substance abuse,
addiction, or illegal market motivations.

**FOLLOW-UP AND NEXT STEPS IN CARE**

It is not generally recommended that a patient with a somato-
form illness be confronted. Instead, the patient should be
reassured that the symptoms do not represent an imminent
threat. Even in cases of malingering, neuropsychologists
rarely confront patients; most use descriptive terminology
rather than the diagnosis “malingering.”

Good charting practices are critical when somatization is
suspected. The history of the present illness and review of
systems should include liberal use of patient quotes to convey
the character of the visit to subsequent providers. Findings on
physical examination also need to be documented carefully
because they may be the reason to pursue or defer diagnostic
intervention. Discharge instructions should ideally include
times, dates, and names of follow-up visits; doses of medica-
tions; and specific return criteria.

The final discharge diagnosis should reflect the chief com-
plaint (e.g., “leg pain”) rather than the suspected somatoform
behavior. This is particularly true of feigned illness because
these diagnoses may have criminal implications. Exceptions
to this rule are suspected intimate partner violence or
Munchausen syndrome by proxy, which deserve special con-
sideration. In both these instances, a high index of suspicion
for the condition is appropriate, and interventions such as
reporting or activating protective services may be required.

Addiction is a personal state of inner tyranny. Addicts hold traditional concerns of family, work, health, and the law as secondary to one primal urge—getting the drug or drink. Many are familiar with the destructive effects of drugs or alcohol for the addict on the street, but most are unaware of the cumulative consequences of addiction on society.

From several viewpoints the problem is vast. Regarding alcohol, the Centers for Disease Control and Prevention reports that approximately 79,000 deaths are attributable to excessive alcohol use annually in the United States, which makes it the third leading lifestyle-related cause of death for the nation. In addition, excessive alcohol use accounts for 2.3 million years of potential life lost annually—an average of about 30 years of potential life lost for each death.1 Concerning drugs, the Substance Abuse and Mental Services Administration of the U.S. Department of Health and Human Services reported that in 2009, 21.8 million Americans used an illegal drug during the month before the survey, which represents 8.7% of the population aged 12 years or older. Illegal drugs include marijuana or hashish, cocaine (including crack cocaine), heroin, hallucinogens, inhalants, and nonmedical use of prescription-type psychotherapeutics.2

Many of those abusing or dependent on alcohol or drugs, or both, disproportionately consume public health care resources, particularly emergency services. Between 1992 and 2000, alcohol-related visits to U.S. emergency departments (EDs) averaged 76 million per year, which accounted for 7.9% of the total ED visits.3 The Drug Abuse and Warning Network reported that in 2007, 1.9 million ED visits were associated with drug misuse or abuse. Although the overall number of ED visits attributable to drug misuse and abuse was stable from 2004 to 2007, ED visits involving nonmedical use of pharmaceuticals with no other drug involvement rose significantly (73%), as did the nonmedical use of pharmaceuticals with alcohol (36%).4

The societal burdens of substance abuse extend well beyond EDs. The U.S. Office of National Drug Control Policy reported that incarcerated offenders were often under the influence of drugs when they committed their offenses and that offenders often commit crimes to support their drug habit. In addition, trafficking in illicit drugs tends to be associated with the commission of particularly violent crimes.5

The cumulative economic cost of substance abuse is astounding. In 1998, alcohol abuse in the United States cost approximately $185 billion, with 47% of this cost simply being due to lost productivity at work.6 The same year, drug abuse in the United States cost $143 billion.7 When adjusted for 2010 dollars, abuse of both drugs and alcohol costs the nation $440 billion—the equivalent of 80% of all revenue raised to fund public education for grades prekindergarten through 12.8 Substance abuse is as much a public crisis for our nation as it is a personal crisis for the addict.

To address the problem of substance-related disorders, we must understand the clinical condition. To understand, we must speak the same language by sharing a common terminology. In general, these disorders are classified not by the quantity of the cause but rather by the effect.

With substance abuse, adverse consequences occur but the pattern has not yet deteriorated into a state of dependence. More specifically, the American Psychiatric Association defines substance abuse as “a maladaptive pattern of substance use” revealed by the recurrent and significant consequences arising from repeated use of the substance: failure to fulfill major role obligations, recurrent use in situations in which it is physically hazardous, multiple substance-related legal problems, and recurrent social and interpersonal problems9 (Box 199.1). Although the consequences of use are significant, some degree of control is present.

In contrast, substance dependence is defined as severe impairment or absence of control. Use is compulsive and occurs under the ever-present threats of tolerance and withdrawal. As stated earlier, the American Psychiatric

---

**KEY POINTS**

- Drug abuse and alcohol abuse irrevocably change brain physiology; addiction represents a brain disorder.
- The acute manifestations of substance abuse and dependency arise from drug-specific patterns of intoxication and withdrawal.
- Acute pharmacologic detoxification is accomplished through the administration of a long-acting medication in the same category as the drug of dependence, thereby blocking withdrawal symptoms.
- Anticraving medications are psychotropic agents that reduce the desire for drugs or alcohol in detoxified patients and prevent relapse into compulsive substance abuse.

**SCOPE, EPIDEMIOLOGY, AND DEFINITIONS**

Addiction is a personal state of inner tyranny. Addicts hold traditional concerns of family, work, health, and the law as secondary to one primal urge—getting the drug or drink. Many are familiar with the destructive effects of drugs or alcohol for the addict on the street, but most are unaware of the cumulative consequences of addiction on society.

From several viewpoints the problem is vast. Regarding alcohol, the Centers for Disease Control and Prevention reports that approximately 79,000 deaths are attributable to excessive alcohol use annually in the United States, which makes it the third leading lifestyle-related cause of death for the nation. In addition, excessive alcohol use accounts for 2.3 million years of potential life lost annually—an average of about 30 years of potential life lost for each death.1 Concerning drugs, the Substance Abuse and Mental Services Administration of the U.S. Department of Health and Human Services reported that in 2009, 21.8 million Americans used an illegal drug during the month before the survey, which represents 8.7% of the population aged 12 years or older. Illegal drugs include marijuana or hashish, cocaine (including crack cocaine), heroin, hallucinogens, inhalants, and nonmedical use of prescription-type psychotherapeutics.2

Many of those abusing or dependent on alcohol or drugs, or both, disproportionately consume public health care resources, particularly emergency services. Between 1992 and 2000, alcohol-related visits to U.S. emergency departments (EDs) averaged 76 million per year, which accounted for 7.9% of the total ED visits.3 The Drug Abuse and Warning Network reported that in 2007, 1.9 million ED visits were associated with drug misuse or abuse. Although the overall number of ED visits attributable to drug misuse and abuse was stable from 2004 to 2007, ED visits involving nonmedical use of pharmaceuticals with no other drug involvement rose significantly (73%), as did the nonmedical use of pharmaceuticals with alcohol (36%).4

The societal burdens of substance abuse extend well beyond EDs. The U.S. Office of National Drug Control Policy reported that incarcerated offenders were often under the influence of drugs when they committed their offenses and that offenders often commit crimes to support their drug habit. In addition, trafficking in illicit drugs tends to be associated with the commission of particularly violent crimes.5

The cumulative economic cost of substance abuse is astounding. In 1998, alcohol abuse in the United States cost approximately $185 billion, with 47% of this cost simply being due to lost productivity at work.6 The same year, drug abuse in the United States cost $143 billion.7 When adjusted for 2010 dollars, abuse of both drugs and alcohol costs the nation $440 billion—the equivalent of 80% of all revenue raised to fund public education for grades prekindergarten through 12.8 Substance abuse is as much a public crisis for our nation as it is a personal crisis for the addict.

To address the problem of substance-related disorders, we must understand the clinical condition. To understand, we must speak the same language by sharing a common terminology. In general, these disorders are classified not by the quantity of the cause but rather by the effect.

With substance abuse, adverse consequences occur but the pattern has not yet deteriorated into a state of dependence. More specifically, the American Psychiatric Association defines substance abuse as “a maladaptive pattern of substance use” revealed by the recurrent and significant consequences arising from repeated use of the substance: failure to fulfill major role obligations, recurrent use in situations in which it is physically hazardous, multiple substance-related legal problems, and recurrent social and interpersonal problems9 (Box 199.1). Although the consequences of use are significant, some degree of control is present.

In contrast, substance dependence is defined as severe impairment or absence of control. Use is compulsive and occurs under the ever-present threats of tolerance and withdrawal. As stated earlier, the American Psychiatric
**PATHOPHYSIOLOGY AND ANATOMY**

Insight into the pathophysiology of substance-related disorders has progressed substantially in recent years. Neuropharmacologic animal studies and human imaging modalities, in particular, positron emission tomography and functional magnetic resonance imaging brain scans, have identified the neurochemical processes and anatomic structures most affected in states of substance abuse and dependence.

Addiction changes brain physiology, thus prompting designation of this condition as a brain disorder. Addictive substances alter multiple neurotransmitter pathways within the brain, including N-methyl-D-aspartate (NMDA) and γ-aminobutyric acid (GABA) receptors, as well as the endogenous opioid, serotonin, and dopamine systems. Changes particularly occur within the mesolimbic system of the brain. Projecting from the ventral tegmental area to the nucleus accumbens, olfactory tubercle, frontal cortex, and amygdala, the mesolimbic system is regarded as the “reward center” of the brain (Fig. 199.1). These neurocircuits presumably evolved to reward survival-enhancing behavior, including productive familial and social interactions, reproduction, and other such behavior. Some suggest that mesolimbic dopamine is a direct mediator of reward, whereas others emphasize that dopamine signals an interest in reward or the expectation that

---

**BOX 199.1 Criteria for Substance Abuse**

A. A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following occurring within a 12-month period:

1. Recurrent substance use resulting in failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
2. Recurrent substance use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
3. Recurrent substance-related legal problems (e.g., arrests for substance-related disorderly conduct)
4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about the consequences of intoxication, physical fights)

B. The symptoms have never met the criteria for substance dependence for this class of substance.

**BOX 199.2 Criteria for Substance Dependence**

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by three (or more) of the following occurring at any time in the same 12-month period:

1. Tolerance, as defined by either of the following:
   a. Need for markedly increased amounts of the substance to achieve intoxication or the desired effect
   b. Markedly diminished effect with continued use of the same amount of the substance
2. Withdrawal, as manifested by either of the following:
   a. The characteristic withdrawal syndrome for the substance (refer to criteria A and B of the criteria sets for withdrawal from the specific substances)
   b. The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
3. The substance is often taken in larger amounts or over a longer period than was intended.
4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.
5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors, driving long distances), use the substance (e.g., chain smoking), or recover from its effects.
6. Important social, occupational, or recreational activities are given up or reduced because of substance use.
7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychologic problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression, continued drinking despite recognition that an ulcer was made worse by alcohol consumption).

Fig. 199.1 Mesolimbic dopaminergic system.
reward is forthcoming. Either way, evidence suggests that the common reinforcing and incentive effects of addictive substances are substantially mediated by increasing extracellular dopamine within the mesolimbic system. On an elementary level, this drug-induced efflux of dopamine is pleasurable.10

As addicts and clinicians mutually recognize, artificially inducing the mesolimbic system with drugs and alcohol for these pleasant effects is accompanied by grave shortcomings. Neurochemical pleasure circuits, overwhelmed by excessive stimulation, adapt by desensitizing.13 Evaluation by multiple disciplines, including anatomic, behavioral, biochemical, and electrophysiologic studies, commonly shows that dopamine neurons function insufficiently in addicts. A hydropaminergic state develops.10 The dopamine deficiency associated with acute withdrawal is manifested clinically as acute dysphoria, depression, irritability, and anxiety. Neurochemically, baseline levels of the “reward” neurotransmitters are depressed.12 The traditional social and behavioral stimulants of the mesolimbic system that function effectively in the nonaddictive state, such as family and positive affirmation from work or friends, become inadequate to generate a significant perception of pleasure. Drugs and alcohol are the sole stimuli sufficient to activate the impaired mesolimbic neurocircuits and generate pleasure.11 Yet even though the baseline mesolimbic system remains hydropaminergic in addicts, the system remains hyperresponsive to abused drugs and alcohol, thereby conferring long-lasting vulnerability even after extensive periods of abstinence.50 The most promising avenues of treatment for addicts are pharmacologic agents aimed at restoring these dopaminergic neurocircuits.50

Not all individuals are equally susceptible. Those with risk-taking and novelty-seeking traits favor the use of addictive drugs. Psychiatric conditions, in particular, schizophrenia, bipolar disorder, and attention-deficit/hyperactivity disorder, are associated with increased risk for substance abuse and dependency. A dual diagnosis of substance abuse and mental disorder has especially unfavorable implications for both management and outcome.14

Genetic factors clearly increase the risk for addiction. First-degree relatives of alcoholics (e.g., parents, siblings, children) have a threefold to fourfold greater prevalence of alcohol abuse than the general population does.13 Men whose parents were alcoholics have an increased likelihood for alcoholism even when adopted at birth and raised by nonalcoholic parents.14 Genetic factors, as revealed by studies in identical twins, account for approximately half of the risk for alcohol abuse.15

Some of this genetic predilection for addiction is expressed through enzymatic variants. For instance, highly active forms of aldehyde dehydrogenase increase alcohol metabolism and decrease the negative side effects of alcohol intake, thereby enhancing consumption and addiction (Fig. 199.2). In contrast, less active variants of aldehyde dehydrogenase (i.e., the ALDH2*2 allele initially detected in eastern Asian populations) allow accumulation of acetaldehyde, the toxic intermediary by-product of alcohol metabolism. Sensitivity to alcohol increases with a subsequent reduction in the rates of alcoholism.16 Genetic influence is also expressed through neurotransmitter variants. Neuropeptide Y, a 36–amino acid peptide neurotransmitter, regulates appetite, anxiety, and reward. A functional Lue7Pro polymorphism in the neuropeptide Y gene increases the risk for alcohol dependence by 7.3%, primarily in European Americans.17 Although the initial use of a drug or alcohol is a willful act, for those predisposed to abuse or dependency, some if not most of what follows is progressively beyond their control.

**PRESENTING SIGNS AND SYMPTOMS**

The signs and symptoms of substance abuse and dependency result from acute states of intoxication and withdrawal. Although some manifestations are specific to the substance, common patterns exist.

Acute intoxication with central nervous system depressants—alcohol, sedatives, hypnotics, and anxiolytics—is characterized by dysfunctional behavioral and neurologic changes. Individuals suffer mood swings and impaired social or occupational functioning. Poor judgment prevails, often reflected by inappropriate sexual or aggressive behavior. Neurologic dysfunction occurs along a clinical spectrum determined by the degree of intoxication and ranges from slurred speech, incoordination, and unsteady gait to impairment of memory and attention, stupor, and coma (Box 199.3). In contrast, acute withdrawal from central nervous system depressants is manifested as physiologic and behavioral agitation. Psychomotor distress can be significant, with transient visual, tactile, or auditory hallucinations. Patients experience autonomic hyperactivity, evident as tachycardia and diaphoresis. Nausea and vomiting may be prevalent, as well as hand tremors. Generalized seizures can occur. Mentally, emotionally, and physically miserable, such patients cannot function.9

Though also central nervous system depressants, opiates confer somewhat unique states of intoxication and withdrawal. Because of the rapid but variable degrees of tolerance that develops to opiates, incremental doses are required to achieve euphoria. However, the unreliable concentration of opiates in street drugs complicates attempts by addicts to self-administer a specific dose. Overdosage frequently results in extreme drowsiness and potentially coma and death from respiratory depression (Box 199.4). In contrast, opiate withdrawal is an extremely unpleasant, conscious experience. Patients experience severe dysphoria, diaphoresis, vomiting, and diarrhea.9
The signs and symptoms of acute intoxication with central nervous system stimulants—cocaíne, amphetamines, and sympathomimetics—are determined by the pattern, route, and amount of drug used, as well as the specific agent. Intermittent “binge” use is often accompanied by euphoria and heightened psychomotor and autonomic activity (e.g., tachycardia, hypertension, seizures, cardiac arrhythmias, chest pain). Chronic daily users have a contrasting scenario. Psychomotor depression and affective blunting may be present, often in the setting of hypotension, bradycardia, and respiratory insufficiency. Withdrawal from central nervous system stimulants occurs after a period of heavy and prolonged use. The withdrawal symptoms of dysphoria, suicidal ideation, extreme fatigue, and hypersomnia are the antithesis of those of acute intoxication.

Emergency physicians often encounter a particularly challenging if not frustrating clinical scenario arising from addiction—drug-seeking activity. Those seeking drugs may engage in “doctor shopping” by visiting multiple outpatient clinics, EDs, and pain management clinics to obtain prescriptions for controlled substances. At times, “scam” situations are presented, such as chronic toothaches, lost or stolen prescriptions, or multiple drug allergies. While recognizing the need to evaluate each situation separately, the physician must be particularly vigilant when patients insist on specific controlled substances, self-assert a high tolerance to medications, or issue veiled threats. Additional clues to drug-seeking behavior are listed in Box 199.6. When in doubt, the signs and symptoms can often be validated through contact with the patient’s personal physician, review of recently issued prescription drugs with the patient’s pharmacist, or perusal of previous medical records.

**BOX 199.3 Diagnostic Criteria for Intoxication with Alcohol, Sedatives, Hypnotics, or Anxiolytics**

A. Recent use of a sedative, hypnotic, or anxiolytic
B. Clinically significant maladaptive behavioral or psychological changes (e.g., inappropriate sexual or aggressive behavior, mood lability, impaired judgment, impaired social or occupational functioning) that developed during or shortly after sedative, hypnotic, or anxiolytic use
C. One (or more) of the following signs developing during or shortly after sedative, hypnotic, or anxiolytic use:
   1. Slurred speech
   2. Incoordination
   3. Unsteady gait
   4. Nystagmus
   5. Impairment in attention or memory
   6. Stupor or coma
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder

**BOX 199.4 Diagnostic Criteria for Opioid Intoxication**

A. Recent use of an opioid
B. Clinically significant maladaptive behavioral or psychological changes (e.g., initial euphoria followed by apathy, dysphoria, psychomotor agitation or retardation, impaired judgment, or impaired social or occupational functioning) that developed during or shortly after opioid use
C. Pupillary constriction (or pupillary dilation as a result of anoxia from a severe overdose) and one (or more) of the following signs developing during or shortly after opioid use:
   1. Drowsiness or coma
   2. Slurred speech
   3. Impairment in attention or memory
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder

**BOX 199.5 Diagnostic Criteria for Cocaine and Amphetamine Intoxication**

A. Recent use of cocaine or amphetamine
B. Clinically significant maladaptive behavioral or psychological changes (e.g., euphoria or affective blunting; changes in sociability; hypervigilance; interpersonal sensitivity; anxiety, tension, or anger; stereotyped behavior; impaired judgment; impaired social or occupational functioning) that developed during or shortly after the use of cocaine or amphetamine
C. Two (or more) of the following developing during or shortly after cocaine or amphetamine use:
   1. Tachycardia or bradycardia
   2. Pupillary dilation
   3. Elevated or lowered blood pressure
   4. Perspiration or chills
   5. Nausea or vomiting
   6. Evidence of weight loss
   7. Psychomotor agitation or retardation
   8. Muscular weakness, respiratory depression, chest pain, or cardiac arrhythmias
   9. Confusion, seizures, dyskinesias, dystonias, or coma
D. The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder

**BOX 199.6 Drug-Seeking Behavior**

- Overreporting of symptoms
- Multiple somatic complaints
- Vague symptom complexes
- Insistence on specific medications
- Refusal of generic equivalents
- Arguments about pharmacology
- Self-asserted high tolerance
- Veiled threats
- Flattery followed by prescription requests
- Demands for polypharmacy
Differential Diagnosis

The differential diagnosis of substance abuse-related disorders is limited (Box 199.7). Hypochondriasis and somatization disorders are generally difficult to distinguish from true addiction in a single ED encounter. Pseudoaddiction describes behavior similar to that of addiction but arising from mismanaged pain. Pseudoaddiction patients are highly focused on obtaining medications, though usually through appropriate routes. They may be “clock watchers” and be focused on the scheduled delivery of approved analgesics. When suspecting a disruption in their expected regimen, a pseudoaddict may become deceptive or overly dramatic in attempts to ensure treatment. As noted, distinguishing between addicts and pseudoaddicts is challenging in an isolated encounter. In a broader perspective, however, pseudoaddicts generally function well once their pain is treated effectively, usually with long-acting opioids.19

*Food and Drug Administration (FDA) approved as an anticonvulsant but potentially effective in preventing alcohol relapse.
†Use in Britain; not currently FDA approved for use in the United States.
‡FDA approved for another indication.

Diagnostic Testing

In contrast to the increasing reliance on technology in diagnosing other medical disorders, the clinical interview remains the best tool for the diagnosis of substance-related disorders. Patients should be questioned about the quantity and frequency of use in an empathetic, nonjudgmental manner. Problems and symptoms current and past should be addressed, including any other family members with substance-related disorders. A number of screening tools are available: CAGE, the Michigan Alcoholism Screening Test (MAST), the Alcohol Use Disorders Identification Test (AUDIT), and the Drug Abuse Screening Test (DAST). These interview tools consist of anywhere from 4 to 28 “yes or no” or multiple choice questions and require from 30 seconds to 7 minutes to complete.20

When substance use is suspected, toxicologic analysis is recommended to establish or confirm a diagnosis. Qualitative analysis is generally sufficient to substantiate drug use, although quantitative levels are indicated for ethanol.

Treatment and Disposition

The treatment goals of substance abuse, in particular, substance dependency, are twofold: detoxification and prevention of relapse (Table 199.1). These objectives are approached through two strategies: pharmacotherapy and behavioral therapy.

Detoxification is a pharmacologic process. The principle of pharmacologic detoxification is straightforward. Patients receive a long-acting medication in the same category as the drug of dependence, thereby blocking withdrawal symptoms. The dosage of this medication is gradually reduced under medical supervision.21

Alcoholics are detoxified with benzodiazepines: lorazepam, diazepam, and chlordiazepoxide. These drugs act by decreasing the hyperautonomic state of alcohol withdrawal by facilitating inhibitory GABA transmission.22 Simultaneous therapy is directed not at alcohol withdrawal per se but rather at frequently associated comorbid conditions, such as malnutrition, and includes thiamine, multivitamins, folate, and magnesium.

Opiate detoxification is managed with two classes of medications: opioid agonists and α2-agonists. The time-tested opioid agonist of broadest use is methadone. The 36-hour half-life of methadone far exceeds the 3- to 4-hour half-life of heroin. Methadone may be prescribed only by maintenance programs approved by the Food and Drug Administration (FDA) and designated state authorities. However, methadone may be used by physicians for temporary maintenance or detoxification if an addicted patient is admitted to the hospital for an illness other than opioid addiction. Methadone may also be used in an outpatient setting when administered daily for a maximum of 3 days while a patient awaits admission to a licensed methadone treatment program.23 Buprenorphine, a partial µ-receptor opioid agonist, has a half-life of 20 to 25 hours and may be prescribed by physicians who have received a waiver by the Drug Enforcement Agency (DEA). α2-Agonists are a commonly used detoxification therapy for mild to moderate opiate withdrawal symptoms in the ED. Activation of presynaptic α2 receptors inhibits sympathetic outflow.24 Currently, only clonidine is available in the United States. However, lofexidine, another α2-agonist similar to clonidine but with a lower incidence of associated hypotension, has been used effectively in Britain for opioid detoxification for more than a decade. Lofexidine will probably be submitted to the FDA for approval based on recent clinical trials.25

Withdrawal from central nervous system stimulants, in particular, cocaine and methamphetamine, is acutely managed with benzodiazepines. As noted earlier, these drugs diminish the hyperautonomic withdrawal state by increasing inhibitory GABA transmission.

**PREVENTION OF RELAPSE**

Prevention of relapse is the second, yet most critical component of treatment because it primarily determines overall morbidity and mortality. Pharmacologic and behavioral therapies, though considered separately, appear to be most effective if combined.

In the past 25 years, a new class of psychoactive medications has emerged that show substantial promise in the treatment of addiction disorders. These “anticraving” medications reduce desire for the drug or alcohol in detoxified patients and deter relapse into compulsive substance abuse.

Three medications have been approved by the FDA for the prevention of alcohol relapse: naltrexone, acamprosate, and disulfiram. As noted earlier in the section “Pathophysiology and Anatomy,” alcohol increases extracellular dopamine in the nucleus accumbens. In mice pretreated with naltrexone, an opioid µ-receptor antagonist, the alcohol-induced increase in dopamine is blocked. These mice do not self-administer alcohol. Similarly, in a study of 99 alcoholic men, naltrexone-treated subjects reported reduced alcohol craving and drinking and decreased alcohol-related euphoria. Relapse rates in naltrexone-treated men were also significantly lower.

Naltrexone can be administered in two formats: an oral daily dosage of 50 mg and depot intramuscular injections of 380 mg every 4 weeks. A metaanalysis of 18 trials of naltrexone for alcohol dependence demonstrated a decrease in the risk for relapse with naltrexone when compared with placebo (relative risk, 0.64; 95% confidence interval, 0.51 to 0.82), as well as a reduction in craving and return to drinking and an increase in time to the first drink. The effect size for reducing relapse was modest (number needed to treat, 7).

Not unexpectedly, daily dosing regimens with naltrexone limit compliance. Depot injections of naltrexone every 4 weeks both enhance compliance and establish more stable therapeutic levels. Three extended-release injectable formulations of naltrexone are available: Vivitrol, Naltrel, and Depotrex.

Acamprosate was approved by the FDA in 2004 for the maintenance of abstinence in detoxified alcohol-dependent patients. The neurochemical effect of acamprosate is attributed to modification of glutamate neurotransmission. Administered orally three times daily, acamprosate is less convenient than either oral or depot naltrexone. In addition, the impact of acamprosate on abstinence is unclear. Several largely positive clinical trials in Europe were contradicted by three negative clinical trials in the United States and Australia. Thus the clinical benefits of acamprosate are equivocal.

Disulfiram blocks aldehyde dehydrogenase, an enzyme fundamental to alcohol metabolism. When someone consumes alcohol while taking disulfiram, acetaldehyde, an intermediate and relatively toxic by-product, accumulates 5- to 10-fold relative to normal circumstances. A most disagreeable clinical consequence, the “disulfiram reaction,” develops. Diaphoresis, headache, dyspnea, hypotension, flushing, palpitations, nausea, and vomiting can all occur. Individuals taking disulfiram have poor compliance because of the unpleasantness of this effect. Disulfiram is administered at 500 mg/day for 1 to 2 weeks, followed by an average maintenance dose of 250 mg/day. Reviews of efficacy show mixed results.

Topiramate, though approved by the FDA as an anticonvulsant, has shown promise in preventing alcohol relapse. A multisite U.S. trial showed that topiramate reduced the percentage of heavy drinking days when compared with placebo (43.8% versus 51.8%) in 371 men and women with alcohol dependence over a period of 14 weeks. Topiramate was also more effective than placebo in improving the secondary outcomes of percent days abstinent and number of drinks per day.

Additional agents under investigation for the prevention of relapse include baclofen, nalmefene, selective serotonin reuptake inhibitors, and ondansetron, among others.

Three medications have been approved by the FDA for the prevention of relapse from opiates: methadone, buprenorphine, and naltrexone. Methadone and buprenorphine act as complete (methadone) or partial (buprenorphine) µ-receptor agonists. Conceptually, methadone and buprenorphine provide long-term replacement therapy for the brain disorder of addiction, comparable with the use of prednisone in patients with adrenal insufficiency or levotheroxine in those with hypothyroidism. Naltrexone, a µ-receptor antagonist, blocks the euphoric effects of opioids. Compliance is relatively poor with naltrexone.

Unfortunately, no medications have been approved by the FDA for the prevention of relapse from cocaine addiction. However, five agents that are FDA-approved for other indications have been found in randomized, controlled trials to be effective for cocaine addiction. Topiramate, modafinil, and vigabatrin affect glutamate and GABA neurotransmission. The mechanism of two others, disulfiram and propranolol, is unknown.

Clinical trials have yet to demonstrate any clear therapeutic options for prevention of relapse from methamphetamine.

**DISPOSITION**

ED patients with substance-related disorders should be referred to behavioral change programs. Success is determined by the pharmacologic anticraving therapy available to prevent relapse and the patient’s intrinsic motivation for change. Multiple behavioral therapies are available to diminish the likelihood of relapse. Contingency management is based on the operant conditioning principle that behavior resulting in positive consequences is more likely to recur. Patients meeting specific drug-free goals receive incentives or rewards. Cognitive behavioral and skills training emphasizes a functional analysis of drug use by taking into account the antecedents and consequences of drug use. Addicts then learn to identify situations at high risk for drug use and relapse. Through rehearsal and role-playing, addicts develop strategies to either avoid such situations or cope effectively. Motivational enhancement therapy (MET) seeks to develop the individual’s inner drive for change. Couples and family treatment takes into account the familial and social systems in which substance use commonly occurs. Alcoholics Anonymous (AA) provides a facilitative form of behavioral therapy that consists of a 12-step program based on self-assessment and fellowship activities.

As noted earlier, pharmacologic and behavioral therapies appear to be most effective when used together. To assess this
that specific patient–behavioral treatment matching is essential for effective treatment of alcoholism. In addition, when compared with their status before treatment, drinking and negative consequences declined regardless of which of the three treatments the participants received. In the outpatient group, 10% more patients receiving TSF achieved continuous abstinence than did those receiving the other two treatments (24% for TSF as opposed to 15% for CBT and 14% for MET).34

Overall, more “aftercare” patients (35%) than “outpatients” (19%) were able to sustain complete abstinence during the year after treatment despite the fact that aftercare patients entered the study with more alcohol dependence symptoms. Although this finding may suggest that an initial period of closely supervised abstinence from alcohol is important to outcome, patients were not randomly assigned to the two cohorts, and other factors may have contributed.

**TREATMENT EFFICACY**

**Alcohol**

The diversity of pharmacologic and behavioral therapies complicates analysis of treatment efficacy. Furthermore, individuals with substance-related disorders differ. No single treatment has been shown to be effective for all.

To better understand the value of particular therapies for alcoholism, the NIAAA initiated Project MATCH (Matching Alcoholism Treatment to Client Heterogeneity) in late 1989. A total of 1726 patients were recruited at treatment facilities throughout the United States. Two parallel cohorts represented the primary formats of treatment: outpatients recruited directly from the community and “aftercare” patients consisting of those who had just completed an inpatient or intensive day hospital treatment program. The three treatment arms included MET, cognitive behavioral therapy (CBT), and a Twelve-Step Facilitation (TSF) program grounded on the 12-step principles of AA but based on professionally delivered individualized therapy rather than therapy in peer groups.34

Project MATCH revealed several notable findings. Most significantly, linking patients to specific behavioral therapies added little to treatment outcome. This disputed the notion...

Anorexia Nervosa and Bulimia Nervosa
Jason E. Liebzeit

KEY POINTS

• Patients with anorexia or bulimia are at increased risk for life-threatening metabolic derangements and cardiac dyshrhythmias that mandate hospital admission.
• The most common cause of death from anorexia is cardiac arrest secondary to conduction delays or ventricular dysrhythmias.
• Urgent outpatient psychiatric referral is appropriate for well-appearing patients who are able to adequately care for themselves.

DEFINITIONS AND EPIDEMIOLOGY

Anorexia nervosa (“anorexia”) is a disturbance in body perception that results in fear of gaining weight and refusal to maintain a minimally normal body weight. Bulimia nervosa (“bulimia”) is an obsessive self-evaluation of body shape and weight that leads to a characteristic cycle of binge eating and subsequent actions that prevent weight gain.

Though similar in their relationship with food, these diseases represent two separate psychiatric entities with distinct clinical sequelae. Distinguishing features include the body mass index or height-matched weight and, in women, the presence of regular menstruation. Amenorrhea is a key finding of anorexia in postmenarchal women. Diagnosis requires fulfillment of all criteria listed in the text revision of the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (Box 200.1). These diseases do not coexist in the same patient; a patient has either anorexia or bulimia, but never both simultaneously.

Anorexia can be divided into the restricting or binge eating–purging subtypes. Restricting patients commonly eat only 300 to 700 calories each day, or they engage in excessive exercise to ward off weight gain. Binge-purging behavior involves intentional vomiting or the inappropriate use of laxatives, enemas, or diuretics in response to even small amounts of consumed food. Bulimia is similarly divided into purging and nonpurging. The subtypes are based on the behavior occurring at the time of diagnosis.

Anorexia and bulimia are diseases nearly exclusively encountered in North America, western Europe, and Japan. Childhood anxiety disorders may increase the likelihood of these disorders, although no clear cause has been identified for either illness. Women suffer from anorexia and bulimia more frequently than men do. The lifetime prevalence of anorexia varies from 0.3% to 1% for women; men are estimated to have one tenth of that prevalence. Bulimia is more common than anorexia, with a lifetime prevalence of 1% to 3% in women. Similarly, only 10% of bulimic patients are male; these men are more likely to suffer from premorbid obesity. The incidence is further increased in male wrestlers.

PRESENTING SIGNS AND SYMPTOMS

Emergency department (ED) patients with anorexia or bulimia generally complain of symptoms related to associated disease states or complications; they rarely seek primary treatment of their psychiatric illness. ED visits provide an opportunity for both intervention and education. Recognition of these under-diagnosed diseases creates an opportunity for early consultation and referral. Medical care alone is often of transient utility. Successful cure of both anorexia and bulimia requires intensive individual or family psychotherapy.

CLASSIC PRESENTATION

The typical patient with anorexia is an otherwise successful mid- to late-adolescent girl exhibiting marked cachexia. The patient may demonstrate a remarkable lack of insight regarding her appearance. Common complaints include fatigue, cold intolerance, abdominal pain, and amenorrhea. Weakness, especially symptomatic orthostasis, features prominently in the patient’s review of systems. Emaciation is the most notable clinical feature. Bradycardia and hypotension are common findings. Lanugo, or the fine body hair commonly seen on the extremities and trunk, may be present. Signs of nutritional deficiency may be present in patients with the food-restricting subtypes.

Patients with the purging subtypes of both bulimia and anorexia share physical findings, although bulimic patients may have a more normal-appearing body habitus. Purging through vomiting often results in erosion of dental enamel, particularly on the lingual (“back”) side of the teeth. Manual induction of vomiting leads to calluses on the dorsal aspect of the fingers as a result of recurrent contact with the teeth, a finding known as the Russell sign. Benign parotid salivary enlargement is common.
Anorexia and Bulimia Nervosa

**Chapter 200**

**ANOREXIA NERVOSA AND BULIMIA NERVOSA**

**ATYPICAL PRESENTATION**
Advances in the management of severe anorexia and bulimia have extended life expectancy for those afflicted. Long-standing anorexia or bulimia affects normal physiology, as with any chronic disease. Notably, gastrointestinal motility may slow and lead to chronic nausea, gastroparesis, impaction, or obstruction. Rare complications of these eating disorders that may be encountered in the ED are discussed in the following section.

“Late-onset” eating disorders are increasingly being recognized in elderly patients; the clinical features and diagnostic criteria are the same, with the exception of amenorrhea in postmenopausal women.

**COMPLICATIONS**

- Arrhythmia: Disruption of normal cardiac conduction is the most life-threatening medical complication of anorexia. Prolongation of the QTc interval is ominous. Cardiac arrest resulting from conduction delays or ventricular dysrhythmias is the most common cause of death from anorexia.
- Elevated abdominal pressure: Patients engaging in binge eating may experience severe gastric dilation that significantly increases intraabdominal pressure, either with or without intestinal obstruction. This increased pressure may ultimately result in cardiac arrest from direct mechanical force or decreased venous return.
- Dehydration and renal insufficiency: Insufficient fluid intake may occur with anorexia. With bulimia, prerenal hypovolemia arises from fluid losses as a result of excessive vomiting or laxative abuse.
- Starvation and vitamin deficiency: These conditions result from inadequate caloric intake.
- Osteopenia: Pubescent anorexia or severe bulimia may cause hypoestrogenemia and resultant undermineralized bone. Bone pain or pathologic fractures may ensue.
- Electrolyte abnormality: This condition results from either insufficient intake or excessive gastrointestinal losses.
- Esophageal and gastric trauma: Repetitive, forceful vomiting may lead to Mallory-Weiss tears or Boerhaave syndrome. Gastric distention occurs with binging.
- Nausea and constipation: Gastrointestinal motility decreases with starvation. Native colonic contraction decreases with laxative abuse, thereby leading to colonic distention and constipation.
- Rectal prolapse: This condition results from muscle weakening secondary to laxative abuse.
- Congestive heart failure: Cardiomyopathy may be caused by starvation states or by ipecac abuse.
- Refeeding syndromes: Peripheral edema, hypophosphatemia, and dysrhythmias are common features associated with resumption of appropriate caloric intake.
- Inattention and changes in mental status: Chronic disease may lead to decreases in both gray matter and white matter along with concurrent ventricular enlargement. Starvation-associated hypoglycemia or other electrolyte abnormalities may affect mental status.

**ASSOCIATED COMORBID CONDITIONS**

- Anxiety disorders: The lifetime prevalence is 64% in eating-disordered patients versus 13% in the general population. Obsessive-compulsive disorder and social phobia are common.
- Depression.
- Substance abuse: This is often seen in patients with binge-type bulimia.
- Personality disorders: Obsessive-compulsive personality disorder is associated with anorexia; cluster B disorders are more frequently identified in patients with bulimia.

**DIAGNOSTIC TESTING**

No ancillary tests are available to confirm the diagnosis of anorexia or bulimia. The diagnosis is made by following the

---

**BOX 200.1 DSM-IV-TR Diagnostic Criteria Differentiating Anorexia and Bulimia**

**ANOREXIA NERVOSA**

1. Refusal to maintain weight greater than or equal to 85% of expected
2. Fear of gaining weight despite being underweight
3. Disturbance in body perception, excessive influence of body shape or weight on self-evaluation, or denial of seriousness of current weight
4. In women of appropriate age, amenorrhea (defined as at least three consecutive missed menses) while not on hormones

Subtype as either restrictive or binge-purge

**BULIMIA NERVOSA**

1. Recurrent episodes of binge eating:
   a. More food in a discreet period than most people would eat in similar circumstances
   b. Sense of lack of control over eating episodes
2. Recurrent inappropriate compensatory behavior to prevent weight gain (vomiting, exercise, laxatives, diuretics)
3. Bingeing and compensatory behavior occurring at least twice per week for 3 months
4. Undue influence of body shape or weight on self-evaluation
5. This disturbance does not occur during an episode of anorexia

guidelines set forth in the DSM-IV-TR. Screening tools have been developed to aid in the diagnosis of both these eating disorders; the SCOFF questionnaire proposed by Morgan et al. is one such tool. Answering “yes” to two or more of the SCOFF questions is 100% sensitive for both anorexia and bulimia. The SCOFF screen includes the following questions: Do you induce vomiting because you feel uncomfortably full? Do you worry that you have lost control over how much you eat? Have you recently lost more than 14 lb in the last 3 months? Do you think you are fat even when other people say you are too thin? Does food dominate your life?

Laboratory tests aid in identification of the potentially life-threatening physiologic abnormalities commonly seen in an eating-disordered patient. Serum electrolytes, including phosphorus, are critical in the evaluation of patients with suspected anorexia or bulimia. Hypokalemia, hypochloremic metabolic alkalosis is the most common finding in patients with induced vomiting. Laxative abuse results in metabolic acidosis from intestinal loss of bicarbonate. Endocrine abnormalities may be encountered in patients with chronic disease; insufficient thyroid hormone may cause hypotension, hypothermia, and bradycardia. An elevated serum amylase level may serve as useful evidence of surreptitious vomiting, although the degree of increase in the serum value itself has little clinical significance (Table 200.1).

An electrocardiogram should be obtained for all patients with suspected anorexia or bulimia. Although bradycardia is a common benign finding in anorexia, other arrhythmias are likely to result in morbidity and mortality. Prolongation of the QTc interval is the most concerning electrocardiographic abnormality and may be present despite normal electrolytes. Intracranial imaging reveals loss of gray matter. Such imaging studies are indicated only for patients with altered mental status or trauma (see the “Priority Actions” box).

**TREATMENT**

ED management should focus on correcting any abnormalities detected during the medical evaluation. Cardiovascular compromise requires immediate intervention. Arrhythmias are managed according to standard advanced cardiac life support guidelines. Electrolytes and glucose should be normalized, and body temperature should be regulated. Aggressive fluid resuscitation should be avoided because it may result in sudden congestive heart failure. The mechanical sequelae of purging (esophageal rupture, Mallory-Weiss tears, or rectal prolapse) respond to conventional treatment discussed elsewhere in this text.

Nutritional support is not a priority in the ED. For outpatients, the intake goal should be 1200 to 1500 kcal/day with weekly increases; weight gain should be limited to 0.5 to 0.9 kg (1 to 2 lb) each week. Inpatient feeding has been associated with life-threatening arrhythmias and transient edematous states; such refeeding is best managed in a monitored medical unit.

Sophisticated and concurrent psychologic, social, dietary, and medical support is crucial for both inpatients and outpatients. Selective serotonin reuptake inhibitors, in particular fluoxetine, have been associated with increased compliance in the outpatient treatment of bulimia and may also address the anxiety states commonly encountered with eating disorders. Antidepressants should not be initiated in the ED without the collaboration of the treating psychiatrist or primary physician.

**DISPOSITION**

Patients generally consent to hospital admission for the treatment of symptomatic somatic complaints. Voluntary admission for psychiatric treatment is often more difficult to arrange. Lack of insight into the disordered eating clouds a
patient’s appreciation of the severity of the disease. Adult patients whose weight is at least 25% less than that expected for their height are candidates for admission.

Telemetry monitoring is indicated when arrhythmias or QTc abnormalities are present. Additionally, refeeding may promote cardiovascular complications, for which continuous monitoring is required. Critical care admission should be reserved for patients with unstable vital signs or dangerous metabolic abnormalities.

Current guidelines suggest psychiatric or medical admission for any child or adolescent with rapid weight loss. Parents or guardians may request inpatient admission when outpatient management has failed. Psychiatric admission for minors is typically easier to accomplish than for adults. Early inpatient treatment is associated with a decreased risk for both arrhythmias and loss of cortical volume. Admission should be advocated for all patients who lack home support or who are otherwise at risk for failure of outpatient treatment (Box 200.3).13,14

Barring clear impairment of decision-making capacity, involuntary admission of adults is rare. The judicial system in the United States generally recognizes that a patient’s actions supersede stated intent, thus supporting hospitalization of patients who are at significant risk for self-harm. For example, an anorexic patient may deny suicidality despite behavior that clearly resulted in a life-threatening dysrhythmia. Involuntary admission should be considered for patients with such profound lack of insight, as well as for those who lack decision-making capacity.5,6

### BOX 200.3 Admission Guidelines

**Medicine**
- Weight less than 25% of expected
- Need for intravenous electrolyte replacement
- Gastrointestinal dysmotility
- Heart failure

**Telemetry**
- QT abnormality
- Stable arrhythmia (i.e., premature ventricular contractions)

**Intensive Care**
- Unstable vital signs
- Life-threatening metabolic derangements

work for an overall cure. Today, oncology patients treated in the emergency department (ED) are increasingly more likely to survive to hospital discharge, even if they are admitted to an intensive care unit.3

TRIAGE

Some oncologic emergencies require timely action. One example is the patient with fever and potential neutropenia; this patient requires rapid assessment and early antibiotic administration. Other oncologic emergencies requiring immediate intervention include airway or respiratory complications, spinal cord compression, and possible cerebral herniation.

ISOLATION AND INFECTIOUS CONTROL ISSUES

Each year, approximately 1.9 million nosocomial infections occur in U.S. hospitals, and approximately 88,000 patients die.4 Immunocompromised patients with cancer, especially neutropenic patients and bone marrow transplant recipients, are at increased risk for these infections. At-risk patients should be identified on ED arrival and should not be allowed to spend a significant amount of time in waiting rooms or busy ED hallways, where they can be exposed to infections from other patients. Ideally, bone marrow transplant recipients and potentially neutropenic patients should be placed in single rooms with positive air pressure at 12 or more air exchanges per hour. Positive air pressure decreases the number of infectious particles that enter a patient’s room. If such a room is unavailable, the next best option is to place the patient in an individual room with the door closed. Patients with a potential airborne illness (e.g., tuberculosis) are the exception; they should be placed in a negative pressure room to protect other patients and the ED staff.

As with all patients, careful hand washing is essential when dealing with the neutropenic patient. However, when providing noninvasive care, the use of sterile gowns, masks, and gloves does not provide any extra protection. To avoid bacterial contamination, neutropenic patients should generally be offered only cooked (or pasteurized) food and bottled water. However, data supporting this type of “neutropenic diet” is quite limited and may unnecessarily restrict the patient’s nutritional options.

EPIDEMIOLOGY

As the population ages, cancer prevalence is expected to increase.1 In 2010, the United States population had more than 1.5 million new cancer diagnoses and more than 569,000 cancer deaths.2 The American Cancer Society estimated that the number of new cancer cases will double from 2000 to 2050.1 At the same time, aggressive treatment strategies, whether involving surgery, chemotherapy, or radiation, are helping oncology patients to live longer and at times overcome their cancer. In fact, U.S. cancer death rates decreased by 1% per year from 2001 through 2006.2 Since the 1970s, the 5-year survival rate for all cancers has increased from 50% to 68% in the United States. Declines in cancer deaths are the result of many factors, including better screening, early detection strategies, public health risk reduction programs, and improved medical and surgical treatment. Emergency physicians (EPs) are routinely called on to recognize and treat emergency complications of cancer and cancer therapies. Interventions that the EP makes to keep a patient alive acutely may allow the patient’s chemotherapy or radiation therapy to
ONCOLOGIC HISTORY

Although obtaining a complete past medical history from a patient with cancer is not always possible or necessary for the EP, certain questions may prove crucial and are unique to the oncology patient. Pertinent information includes the type of cancer, the stage of the cancer (the extent of its spread), previous cancer-related complications, and previous cancer treatments including surgery, chemotherapy, and radiation therapy. The timing of recent treatments and the names of specific chemotherapeutic agents that have been used are important because these treatments may be the direct cause of the patient’s current illness. Oncology patients may have complicated past medical histories. Reliable sources such as hospital records (if the patient has recently been admitted) or the patient’s oncologist should be used to obtain pertinent data quickly.

Early in the ED encounter with an oncology patient, the patient should be asked whether he or she has any specific wishes or advanced directives. Specifically, patients should be asked whether they have a “do not resuscitate” or “do not intubate” order or a health care proxy. Many patients with cancer, especially those with late-stage disease, may have very defined treatment objectives in mind (e.g., intravenous hydration but no invasive procedures or tests). These objectives and wishes should be documented in the chart and respected. Early inquiry about the patient’s wishes and expectations will help to guide treatment appropriately.

FEVER

Fever is a very common chief complaint for oncology patients who present to the ED, especially for those undergoing chemotherapy. Fever can be the first sign of a life-threatening infectious process. In particular, neutropenic patients are highly susceptible to almost any type of bacterial or fungal infection. Fever in the setting of neutropenia must be assumed to be a life-threatening bacterial infection, and antibiotic therapy should be started immediately (see the “Facts and Formulas” box for the definition of neutropenic fever). Besides the immediate infectious risks, a neutropenic fever episode may delay or end future chemotherapy treatment and therefore may compromise the overall chances for a cancer cure.

PATHOPHYSIOLOGY

Chemotherapy can severely damage a patient’s normal defense mechanisms, including both humoral and cellular immunity, thus leaving the patient defenseless to combat infection. Chemotherapy can weaken or destroy neutrophils, T lymphocytes, macrophages, monocytes, and immunoglobulin production. Radiation and chemotherapy also affect the patient's mechanical barriers against infection. In particular, they damage the integrity of the mucous membranes and skin. All this injury to the patient’s immune system takes place in an individual who already has cancer and therefore may already have either a weakened immune system or compromised physiologic factors.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Although the prudent approach is to assume that fever in an oncology patient is from an infectious source, infection is not the only reason that oncology patients may have a fever. Fever can sometimes be a manifestation of the underlying malignant process itself or a side effect of a chemotherapeutic agent. Chemotherapeutic agents such as bleomycin and cytosine arabinoside have been noted to cause fevers. Lymphomas, leukemias, and renal cell carcinoma have been recognized as sources of fever without any concurrent infection, and at times, fever can be their initial presenting symptom. Thrombophlebitis, medications, and transfusion reactions can also be rare causes of fever.

DIAGNOSTIC TESTING

The EP should search for an infectious source of the fever. A minimum evaluation should include at least two blood cultures, a urinalysis and urine culture, a chest radiograph, a complete blood count with differential (to confirm neutropenia), and baseline chemistry studies including kidney and liver function. Blood cultures should be obtained from all indwelling vascular catheters that are present. At least one blood culture should be drawn from a peripheral vein. Further diagnostic testing should be driven by the patient’s symptoms or physical examination findings. For example, an abdominal and pelvic computed tomography (CT) scan should be ordered if an intraabdominal source of the fever is possible. Other sources to consider culturing in the appropriate clinical setting are the oropharynx, cerebrospinal fluid, peritoneal fluid, pleural fluid, stool, and any purulent skin lesions.

TREATMENT

Empiric, broad-spectrum antibiotics should be started as early as possible for patients in the ED who have neutropenic fever. Antibiotics should not be delayed while awaiting confirmation...
of the neutropenia but rather should be started on all febrile patients at high risk (e.g., recent chemotherapy). Additionally, antibiotics should not be delayed while the EP looks for an infectious source. An obvious source is very often not identifiable in the ED. Rapid antibiotic administration is the likely reason for substantial mortality reductions among bacteremic patients with cancer. With the incorporation of this early antibiotic strategy, a large European research group found an overall mortality decrease from 21% to 7% over a 16-year period.7

Patients should be started empirically on antibiotics that reflect the resistance patterns and bacterial profiles of the treating institution. Most institutions have antibiotic protocols based on these bacterial patterns. Gram-positive organisms such as Staphylococcus aureus, Staphylococcus epidermidis, and viridans streptococci are currently more predominant than gram-negative organisms as the source of neutrophenic fever. However, gram-negative organisms can be more virulent (e.g., Pseudomonas), and therefore the patient must always be empirically treated for these pathogens.

Single-agent intravenous antibiotics regimens are currently recommended for hemodynamically stable patients whose medical condition is uncomplicated.6,8 Potential monotherapy regimens include cefepime, piperacillin-tazobactam, or a carbapenem (e.g., imipenem-cilastatin, meropenem).6,8 Double coverage with an aminoglycoside (e.g., gentamicin, tobramycin) or a fluoroquinolone (e.g., levofloxacin) should be considered if antibiotic resistance is strongly suspected, if the patient is in shock, or if this approach is needed to manage other complications. Vancomycin should not be started empirically for neutrophenic fever.6,8 No significant difference in morbidity or mortality was found in a meta-analysis of 13 randomized control trials when a standard neutropenic antibiotic regimen was compared with the same regimen plus a glycopeptide (e.g., vancomycin). However, one should consider starting vancomycin if the infection is suspected to originate from an indwelling central venous catheter, a soft tissue infection, or hospital-associated pneumonia or if the patient is in septic shock.6,8 A lower threshold for adding vancomycin should be used if the institution has a high rate of methicillin-resistant S. aureus (MRSA) or resistant viridans streptococcal strains.

Long indwelling catheters should generally be left in place and not removed in the ED. Many catheters in this patient population are buried subcutaneously and are not easily removed. Removal of the catheter in the ED should be considered if the tunnel is grossly infected or if the infected catheter has produced septic emboli or endocarditis.

Granulocyte colony-stimulating factors (G-CSFs) are used by oncologists with certain chemotherapy regimens to decrease the incidence of neutropenic episodes. Current guidelines recommend the prophylactic administration of a G-CSF with chemotherapy to patients who, based on age, past medical history, chemotherapy toxicity, and tumor characteristics, have a greater than 20% chance of developing febrile neutropenia.6,10 This G-CSF prophylaxis regimen with chemotherapy has been shown to be effective; for example, in patients with small cell lung cancer, it decreases the incidence, duration, and severity of neutropenic fever.11 Commonly used G-CSFs for prophylaxis are daily injections of filgrastim or lenograstim or a once per chemotherapy cycle injection of pegfilgrastim. Adverse side effects of G-CSF use include bone, joint and musculoskeletal pain and flulike symptoms.6,8

The use of a G-CSF in the acute setting of neutropenic fever is controversial. A meta-analysis of 13 studies with 1518 patients found that patients with neutropenic fever who were treated with G-CSFs had shorter hospitalizations and neutrophil recovery times but only a marginally significant benefit in infection-related mortality and no significant benefit in overall mortality.12 Because the effects of G-CSFs on mortality are not clear and because these agents are very expensive, a G-CSF should not be given routinely in the ED for neutropenic fever. Rather, until more convincing evidence exists, G-CSFs should be given only after discussion with the patient’s oncologist and considered only for patients who are at high risk for infectious complications or who have prognostic factors predictive of a poor outcome.10,13

**FOLLOW-UP AND NEXT STEPS**

Nearly all patients with neutropenic fever require admission. Outpatient management could be considered for carefully selected low-risk patients within a well-designed institutional protocol and in concert with the patient’s oncologist. Certain decision rules have attempted to determine which neutropenic patients are at low risk for complications and therefore could be eligible for outpatient treatment with oral antibiotics. The most commonly cited decision rule for assessing low-risk patients is the Multinational Association for Supportive Care in Cancer (MASCC) index score (Table 201.1). In its initial implementation, the MASCC index score was developed in an effort to identify low-risk patients based on the probability of complications and the risk associated with those complications. Patients with a low-risk score (3 or less) were found to have a low risk of complications and were recommended for outpatient treatment. Patients with a high-risk score (4 or more) were recommended for inpatient treatment. The MASCC index score is calculated based on the presence of fever, age, recent chemotherapy, and the type of chemotherapy agent used. The score is determined by adding points for each of these factors and then comparing the total score to the risk of complications.

validation study, the MASCC index score was found to have a positive predictive value of 91%, a specificity of 68%, and a sensitivity of 71%. The MASCC decision rule is likely best applied to select patients who can quickly undergo conversion to oral antibiotics as inpatients and, in the absence of early complications, be targeted for early hospital discharge. If the patient is discharged, an oral antibiotic regimen is prescribed; ideally, the patient is observed taking the first dose in the ED. The two most common regimens used are a quinolone alone (e.g., ciprofloxacin) or a quinolone plus amoxicillin-clavulanate.

**INFECTION CAUSES OF FEVER UNIQUE TO THE PATIENT WITH CANCER**

**NEUTROPENIC ENTEROCOLITIS (TYPHLITIS)**
Typhilitis (neutropenic enterocolitis) is an inflammatory process of the ileum and colon that affects neutropenic patients. Typhilitis is most commonly associated with acute leukemia, but it can be seen with other malignant conditions. Typhilitis usually occurs in patients undergoing chemotherapy, although it occasionally occurs in patients who are not. Presenting clinical symptoms may include fever, lower abdominal pain, and diarrhea, which can be bloody or watery. Other potential symptoms include abdominal distention and nausea or vomiting. On physical examination, the patient’s abdomen may be generally tender, or the tenderness may be localized to the right lower quadrant. CT scan can make the diagnosis and rule out other potentially dangerous abdominal processes (e.g., appendicitis, diverticulitis). Typical CT scan findings of typhilitis are diffuse submucosal thickening of the affected bowel wall, generally the terminal ileum or ascending colon. Other CT scan findings may include paracolic fluid and gas in the bowel wall. Uncomplicated cases should be treated with broad-spectrum antibiotics (covering aerobic and anaerobic pathogens, including *Pseudomonas aeruginosa*), bowel rest, and supportive care. Patients who present with perforation, obstruction, bleeding, or gangrenous bowel require prompt surgical consultation. The mortality rate of typhilitis is quite high; in one case series, six of nine patients died of sepsis.

**FUNGAL INFECTIONS**
Fungal infections increasingly are the likely source of the infection when neutropenic patients with cancer have persistent fevers despite ongoing broad-spectrum antibiotics. *Candida albicans* is the most common fungal pathogen in these cases, but aspergillosis, cryptococcus, and other fungal infections can occur. In oncology patients with neutropenic fever, invasive candidiasis and aspergillosis are associated with high mortality rates (36.7% and 39.2%, respectively). Patients with leukemia, in particular, have increasing incidences of fungal infections, especially with *Candida* species. Empiric antifungal therapy should be considered in neutropenic patients with persistent fever despite 4 to 7 days of antibiotic therapy.

**INVASIVE FUNGAL SINUSITIS**
Invasive fungal sinusitis affects immunocompromised patients and has a high mortality rate. *Aspergillus* and species of the Mucoraceae family (usually *Rhizopus*) are the most common fungi involved; they can destroy both tissue and bone. Fungal infection of the paranasal sinuses becomes acute invasive fungal sinusitis as it spreads through tissues to the orbit or the central nervous system. Patients with acute invasive fungal sinusitis may appear severely ill. Symptoms include fever, nasal congestion, headache, maxillary tenderness, periorbital swelling, and even mental status changes. Conversely, in an immunocompromised patient with cancer, symptoms may be subtle because the patient may not mount enough of an inflammatory response to produce clinical symptoms. Therefore, the clinician must maintain a high index of suspicion in this patient population. If the disease is suspected, immediate consultation with an otorhinolaryngologist for surgical débridement is imperative. A CT scan of the sinuses may be helpful to define the extent of the disease, but imaging should not delay surgical consultation. Intravenous antifungal therapy should be initiated with amphotericin B; however, antifungal therapy may not be effective without wide surgical débridement.

**TUMOR LYsis SYNDROME**
Tumor lysis syndrome (TLS) is the constellation of metabolic abnormalities that occur in response to the rapid destruction of malignant cells, generally from the initiation of chemotherapy (Table 201.2). The sudden death of many malignant cells results in the release into the bloodstream of their intracellular contents, and this causes sudden increases in potassium, phosphorus, and uric acid levels. TLS is generally

| **Table 201.2** Tumor Lysis Syndrome: Electrolyte Disturbances and Treatment |
|-----------------------------|-----------------------------------------------|
| **DISTURBANCE**             | **TREATMENT**                                 |
| Hyperkalemia                | Sodium polystyrene sulfonate, regular insulin and glucose, calcium gluronate; if severe: dialysis |
| Hyperphosphatemia           | Aluminum hydroxide; if severe: dialysis        |
| Hypocalcemia                | Calcium gluconate (only if symptomatic)        |
| Uremia                      | IV hydration; IV rasburicase (recombinant urate oxidase) |
| Renal failure               | Dialysis                                      |

IV, Intravenous.
predictable. It usually occurs with the initiation of chemotherapy in a patient with newly diagnosed cancer. Acute lymphoblastic leukemia, acute myeloid leukemia, and non-Hodgkin lymphoma (especially Burkitt lymphoma) are the most common cancers associated with TLS.\textsuperscript{17} Less commonly, TLS occurs in other leukemias, in multiple myeloma, or after the treatment of some solid tumors such as breast and lung cancer. When initiating chemotherapy, oncologists generally take measures to prevent TLS in at-risk patients by pretreatment with aggressive hydration, diuresis, and allopurinol (in an attempt to decrease uric acid formation). Rarely, TLS develops spontaneously. When it does, it is usually in the setting of relapsing or newly diagnosed (but untreated) cancer.

**PATHOPHYSIOLOGY**

TLS most frequently occurs when the patient has a high tumor burden that is very sensitive to chemotherapy. Chemotherapy rapidly destroys malignant cells; intracellular nucleic acids are released and are broken down into uric acid. Uric acid, which is renally excreted, precipitates in the renal tubules. The precipitation may obstruct flow and can result in renal failure. Clearly, patients with baseline renal dysfunction are at even greater risk. Potassium, found in high concentrations intracellularly, is released with the destruction of the malignant cells. Because of worsening renal function secondary to uric acid precipitation, the kidneys are unable to clear this excess potassium, and the result can be dangerously high potassium levels. Phosphorus is similar to potassium; it is concentrated intracellularly and is generally excreted by the kidney. Therefore, phosphorus levels also rise. The excess phosphorus congregates with available calcium to form calcium phosphate crystals that cause the calcium level to drop. These crystals may precipitate in the renal tubules and worsen renal function.

**PRESENTING SIGNS AND SYMPTOMS**

TLS manifests with symptoms reflective of the metabolic abnormalities that are present (e.g., hyperkalemia, renal failure). Therefore, symptoms may be nonspecific. Symptoms of hyperkalemia tend to be vague and may include palpitations, paresthesias, fatigue, muscle cramps, nausea, and weakness; examination findings may include nonfocal reduced muscle strength or decreases in deep tendon reflexes. Mild hypocalcemia causes muscle cramps, paresthesias, and minor mental status changes. With severe hypocalcemia, the patient may have significant mental status changes, tetanic contractions, seizures, hypotension, or dysrhythmias. Classic physical examination findings include the Chvostek sign (facial twitching or spasms with tapping over the facial nerve anterior to the ear) and the Trousseau sign (carpal spasm with inflation of a blood pressure cuff above the systolic blood pressure). Very high levels of phosphorus can cause vomiting, diarrhea, lethargy, and even seizures.

**DIAGNOSTIC TESTING**

Laboratory evaluation should include, at minimum, blood urea nitrogen, creatinine, potassium, calcium, magnesium, phosphorus, uric acid, albumin, and urinalysis. The measurement of ionized calcium may be helpful. An electrocardiogram (ECG) should be obtained because it can quickly help diagnose significant hyperkalemia or hypocalcemia. A chest radiograph may be useful if the EP is concerned about fluid overload secondary to renal failure.

**TREATMENT**

Despite the widespread oncologic practice of prophylactic measures to prevent TLS, the EP occasionally must manage this potentially life-threatening syndrome. A high index of suspicion must be kept for this clinical entity, especially in high-risk patients who recently started chemotherapy or who may have baseline renal insufficiency. Patients with suspected TLS should be placed on continuous cardiac monitoring because they are at risk for cardiac dysrhythmias. Treatment should be focused on closely monitoring electrolytes and renal function, correcting electrolyte abnormalities, and ensuring appropriate hydration. Patients who do not have acute renal dysfunction should be aggressively hydrated with normal saline solution. Aggressive hydration helps renal blood flow and the excretion of potassium, uric acid, and phosphorus. After adequate hydration, furosemide or mannitol may be added to increase urine output.

Hyperkalemia and hyperphosphatemia should be promptly treated. Only symptomatic hypocalcemia should be treated because infusing calcium into a hyperphosphatemic patient increases the risk of calcium phosphate formation and deposition throughout the body, including in the renal tubules. In clinically significant TLS (e.g., renal dysfunction, hyperuricemia), rasburicase, a recombinant form of urate oxidase, can be used. Urate oxidase is an enzyme (not found in humans) that converts uric acid to allantoin, which is 5 to 10 times more water soluble than uric acid. The recommended rasburicase dose is 0.1 to 0.2 mg/kg/day intravenously in 50 mL of normal saline solution over 30 minutes.\textsuperscript{17} Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency. Allopurinol, which has been traditionally used in the prevention and treatment of TLS, works by decreasing uric acid production through competitive inhibition of the enzyme xanthine oxidase, which turns xanthine into uric acid. Once uric acid is present, allopurinol’s effect is limited; therefore, allopurinol is not very useful in the acute treatment of TLS.\textsuperscript{17} Finally, when renal failure develops and becomes severe (e.g., uncontrolled hyperkalemia, uncontrolled hypertension, fluid overload), emergency hemodialysis is indicated.

Controversy exists regarding the practice of urine alkalization, which consists of adding sodium bicarbonate to intravenous fluids in an effort to help excrete uric acid. The theory is that alkalization (with a goal of achieving a urine pH of 7 to 7.5) decreases uric acid precipitation in the renal tubules and increases uric acid excretion in the form of urate. Although a sodium bicarbonate infusion may help to eliminate uric acid, it may also worsen hypocalcemia and increase phosphate and calcium precipitation, potentially in the heart and kidneys, and therefore worsen renal function. Because hydration alone may achieve adequate uric acid excretion, routine urine alkalization is not currently recommended.\textsuperscript{17}
**HYPERCALCEMIA**

**EPIDEMIOLOGY**

Hypercalcemia is the most common metabolic abnormality found in patients with cancer. At some point in their illness, at least 10% to 30% of patients with cancer develop hypercalcemia. Unfortunately, the diagnosis is frequently missed and left untreated because the symptoms are nonspecific and are often attributed to other causes (e.g., chemotherapy, infection). Hypercalcemia is most commonly found in breast and lung cancer, but it also occurs in multiple myeloma, leukemias, lymphomas, and cancers of the head, neck, kidney, and gastrointestinal tract.

**PATHOPHYSIOLOGY**

Primary hyperparathyroidism is the most common cause of an elevated calcium level in patients who do not have cancer. In malignant disease, hypercalcemia is related not to parathyroid hormone activity, but rather to increased osteoclastic activity in bone. A few mechanisms are responsible for this increased osteoclastic activity. First, metastasis of solid tumors can cause extensive direct bone destruction. Some cancer cells release osteoclast-activating factors. Some cancers produce a parathyroid-like hormone that acts on bone by increasing calcium uptake and also acts on the kidneys by decreasing calcium excretion.

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms of hypercalcemia are generally nonspecific. Symptom severity depends more on how rapidly the calcium level has escalated, rather than on the actual calcium level. Symptoms include general weakness, constipation, nausea and vomiting, dehydration, polyuria and polydipsia, personality changes, and bone and muscle pains. Severe symptoms include confusion, drowsiness, and even coma. No physical examination findings are specific only to hypercalcemia. However, the diagnosis must be considered when evaluating an oncology patient with any degree of mental status alteration (from mild confusion to obtundation), hyporeflexia, or dehydration.

**DIAGNOSTIC TESTING**

If hypercalcemia is suspected, an ECG should be performed and laboratory tests sent for, at minimum, creatinine, potassium, calcium, phosphate, alkaline phosphatase, and albumin. QT shortening on the ECG may provide the quickest method of diagnosing hypercalcemia. In patients with higher calcium levels, the ECG may have a variety of finding, including T-wave changes, bradycardia, or heart block. The calcium level reported in a basic metabolic profile reports the calcium concentration in serum, the normal value of which is 9 to 11 mg/dL. Calcium levels greater than 12 mg/dL should generate concern, and levels higher than 14 mg/dL require immediate intervention. However, calcium levels correlate poorly with actual symptoms. Because calcium is present both in an ionized form and a protein-bound form, the concentration of calcium depends on plasma protein concentrations. A corrected calcium level should be calculated to assess whether hypercalcemia is truly present (see the “Facts and Formulas” box). The corrected calcium concentration is based on the albumin level. After this calculation, if any uncertainty remains, an ionized calcium level should be obtained.

**TREATMENT**

Correcting hypercalcemia not only improves symptoms, but it also may decrease the risk of death during hospitalization.

For initial treatment of significant hypercalcemia, aggressive intravenous hydration with normal saline solution should be started. Hypercalcemic patients may be significantly volume depleted and require intravenous fluids. Saline hydration dilutes the calcium concentration, promotes urinary excretion of calcium, and treats dehydration. Patients with severe hypercalcemia should be placed on continuous cardiac monitoring, and their urine output should be closely monitored (with a Foley catheter if necessary).

Electrolyte studies should be obtained every few hours to monitor the calcium level and to ensure that the saline hydration does not cause significant hypokalemia or hypomagnesemia. If the patient is in renal failure and will not tolerate aggressive saline hydration, dialysis may be needed to correct the calcium level.

In addition to saline hydration, a bisphosphonate should be considered (e.g., pamidronate, zoledronic). Bisphosphonates work by inhibiting osteoclastic activity through prevention of osteoclast attachment to bone and interference with osteoclast recruitment; this process decreases bone reabsorption. Pamidronate, the most commonly used bisphosphonate, can be administered at 60 mg intravenously over 2 to 24 hours for moderate hypercalcemia and at 90 mg over 2 to 24 hours for severe hypercalcemia. Another bisphosphonate, zoledronic acid, 4 mg intravenously, may be more effective.

Calcitonin should be considered next. Calcitonin inhibits bone reabsorption and increases renal excretion of calcium. The effects of calcitonin are short-lived, but they can be seen within 4 hours. Calcitonin is administered at 4 to 8 units/kg either intramuscularly or subcutaneously.

Even though loop diuretics (e.g., furosemide) are unlikely to lower the calcium level significantly, they may be useful if the patient becomes volume overloaded and needs diuresis. Before a diuretic is administered, the patient should have
demonstrated adequate urine output; this will ensure that the diuretic will not worsen a volume-depleted state.

Other possible treatments for hypercalcemia include gallium nitrate, mithramycin, and corticosteroids (e.g., hydrocortisone). These agents can be administered in consultation with the patient’s oncologist. Finally, patients with mild calcium elevations or minimal symptoms can be treated with oral hydration.

**FOLLOW-UP, NEXT STEPS, AND ADMISSION AND DISCHARGE**

Patients with mild calcium elevations can be discharged after hydration in the ED. Discharge can be considered if patients have no other active issues and if close follow-up can be arranged with their oncologist. Patients with significant symptoms (e.g., dehydration, altered mental status) should be admitted, as should patients with baseline renal insufficiency, because they are more difficult to treat.

**HYPOTENSION**

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The causes of hypotension or shock in an oncology patient in the ED vary to some degree from those seen in the general ED population (Box 201.1). Common causes of hypotension and shock, such as sepsis and hypovolemia (e.g., secondary to gastrointestinal losses or bleeding), are also common in the oncology patient. Severe dehydration is a particular problem because many cancers or cancer treatments make oral intake very difficult and may cause vomiting or diarrhea. Certain clinical entities such as pericardial tamponade and adrenal insufficiency appear with increased frequency in this patient population. Cardiac tamponade is discussed in Chapter 202, but the EP must always consider this disorder in any patient with cancer who presents with hypotension, shock, or dyspnea. Some causes of hypotension are unique to the patient with cancer, such as myocardial dysfunction from a chemotherapeutic agent (e.g., doxorubicin). Because oncology patients are immunocompromised at baseline, they may require more intensive management and may suffer a worse outcome if hypotension is not addressed promptly.

**ADRENAL INSUFFICIENCY**

**PATHOPHYSIOLOGY**

In the oncology patient, adrenal insufficiency is most commonly a result of previous treatment with high-dose steroids used in chemotherapy protocols. Many patients with cancer may have subclinical or mild adrenal insufficiency that is not asymptomatic until a significant stress (e.g., infection, dehydration) develops. Adrenal insufficiency can be primary if the adrenal glands are destroyed in some way (e.g., hemorrhage, infarction) or secondary if dysfunction of the hypothalamic-pituitary-adrenal axis causes a deficiency of adrenocorticotropic hormone. Previous exogenous steroid use is a secondary cause. Metastatic infiltration of the adrenal glands is not uncommon because of the adrenal’s rich blood supply; however, metastatic infiltration rarely causes adrenal insufficiency. In one study, only 4.3% (20 of 464) of patients with metastasis to the adrenal glands on CT scan had or developed symptomatic adrenal insufficiency before they died.21 Metastasis to the adrenal glands is most common in lung cancer, gastrointestinal malignant disease (stomach, esophagus, liver, pancreas, and bile duct), lymphoma, kidney cancer, and breast cancer.21

**PRESENTING SIGNS AND SYMPTOMS**

Adrenal insufficiency manifests with vague symptoms such as fatigue, weakness, nausea, vomiting, nonspecific abdominal pain, dehydration, and altered mental status. Laboratory analysis may show any combination of hyponatremia, hyperkalemia, or hypoglycemia. When severe, acute adrenal insufficiency (“adrenal crisis”) produces significant hypotension secondary to distributive shock that may not respond to aggressive fluid resuscitation. The EP must have a high index of suspicion for this entity because the symptoms are often vague and can be incorrectly attributed to other causes.

**DIAGNOSTIC TESTING**

According to consensus guidelines, adrenal insufficiency (in the setting of critical illness) can be diagnosed with either a random total cortisol level of less than 10 mcg/dL or by cortisol level nonresponse (less than 9 mcg/dL) to the 250-mcg short corticotropin-stimulation test.22 The short corticotropin-stimulation test can be performed by administering 250 mcg of cosyntropin intravenously after a baseline cortisol level is obtained. The cortisol level is repeated 30 and 60 minutes later. If the patient has adrenal insufficiency, the cortisol level response will be less than 9 mcg/dL (the difference between the baseline level and the highest response).23 In an effort to increase the sensitivity of detecting adrenal insufficiency, the corticotropin-stimulation test with 1 mcg was studied, but further outcome data are needed.24 If etomidate, which selectively inhibits 11-β-hydroxylase, is used in the ED course
(specifically in the previous 4 hours), it may interfere with the cortisol response to corticotrophin. This may give a false-positive result to the corticotropin-stimulation test and the clinician may falsely conclude that the patient is adrenally suppressed.25

**TREATMENT**

The treatment of adrenal insufficiency consists of glucocorticoid replacement. The most commonly recommended glucocorticoid is hydrocortisone (initial dose, 100 mg intravenously). Dexamethasone may be preferred over hydrocortisone because dexamethasone is less likely to interfere with the corticotropin-stimulation test, which can be performed later by the inpatient team or in the ED to confirm the diagnosis. A serum cortisol level can be obtained before steroid therapy is initiated. Hypotension, or dehydration is likely to be present and should be treated with fluid resuscitation (either with normal saline solution or 5% dextrose in normal saline). Any electrolyte abnormalities, especially hypoglycemia, should be promptly corrected.

**Myocardial Dysfunction Secondary to Chemotherapy**

As in the general population, the most common cause of cardiac dysfunction or cardiogenic shock in the oncology population is coronary artery disease. Oncology patients, like any other patient who presents in congestive heart failure or cardiogenic shock, must be evaluated for myocardial infarction. However, a few chemotherapeutic agents, most notably the anthracyclines, can cause cardiomyopathies and congestive heart failure (Table 201.3). A newer drug, trastuzumab (Herceptin), which is a recombinant monoclonal antibody used in the treatment of breast cancer, has been associated with reductions in left ventricular ejection fraction and episodes of congestive heart failure.26

**Dyspnea and Airway Issues in the Oncology Patient**

**AIRWAY MANAGEMENT**

**PATHOPHYSIOLOGY**

When managing the airway of the oncology patient, the EP must keep some unique issues in mind. Challenging airway situations may develop in patients with certain head, neck, and laryngeal cancers or with cancers of the esophagus, thyroid, or lung whose tumor has impinged on or distorted the airway. Metastatic lesions to the bronchial tree, mediastinal structures, or lymph nodes of the neck may also cause difficulties. The major concern in these patients is that typical rapid-sequence intubation with a paralytic agent may turn a nonobstructing airway lesion into a lesion that, in a patient without any muscular tone, completely obstructs the airway and makes endotracheal intubation and bag-valve mask ventilation difficult or impossible.

**TREATMENT**

Clues to a potentially hazardous airway may include complaints of dyspnea (especially if it is worse in the supine position), stridor, hemoptysis, difficulty with handling secretions, hoarseness, or a recent change in voice. If the EP is concerned about paralyzing the patient, a few options exist.

*CHF, Congestive heart failure. |
*These effects may be acute.
One option is to give the patient topical and nebulized lidocaine and a small dose of a sedative (e.g., midazolam, etomidate) and then perform direct laryngoscopy. If the vocal cords can be visualized with this approach and no obvious concerns for airway obstruction are noted, the patient should be either directly endotracheally intubated or intubated with typical rapid-sequence intubation using a paralytic agent. If airway control is not an emergency, awake fiberoptic intubation may be a prudent approach. Whatever method is taken, a cricothyroidotomy kit should be at the bedside, in the event that endotracheal intubation proves impossible. Even cricothyroidotomy may be difficult if the patient has significant alterations in neck anatomy secondary to neck cancer or previous neck radiation.

Specialist consultation (e.g., pulmonology, oncology, thoracic surgery) may be helpful if concern exists that a malignant tumor may be impinging on the airway, but the airway does not need to be secured on an emergency basis. In this nonemergency setting, a specialist may use one of several treatment options, including self-expanding stents (placed by rigid bronchoscopy), airway dilatation (by flexible bronchoscopy), laser therapy, radiation, or chemotherapy.

Difficult airways may arise in oncology patients who have severe mucositis or bleeding disorders. Mucositis, especially, may make the tissues of the airway and oropharynx extremely friable, and the tissues may bleed easily with any manipulation; this problem makes standard endotracheal intubation more challenging. Many patients with cancer have significant thrombocytopenia. Special care must be taken with these patients because multiple or traumatic airway attempts may cause significant bleeding into the airway that may be difficult to control. Rarely performed, nasotracheal intubation, which may cause trauma to the nasal passages, should be avoided in patients with mucositis or bleeding disorders.

**MALIGNANT PLEURAL EFFUSIONS**

**PRESENTING SIGNS AND SYMPTOMS**

Pleural effusion is a common cause of dyspnea in the patient with cancer who presents to the ED. Malignant pleural effusions are most commonly seen in patients with lung and breast cancers but are also seen with lymphoma and ovarian and gastric cancers. The diagnosis of a malignant pleural effusion is associated with increased 6-month mortality. The dyspnea of pleural effusions is generally progressive and may occasionally be associated with cough or chest pain. A chest radiograph usually enables the EP to make this diagnosis. Ultrasound can be useful to diagnose pleural effusion quickly and can simultaneously exclude pericardial effusion or cardiac tamponade. A chest CT scan can confirm the diagnosis and may be especially helpful because it can simultaneously rule out other life-threatening causes of dyspnea (e.g., pulmonary embolism, pneumonia).

**TREATMENT**

Thoracentesis should be performed for highly symptomatic patients. Removing pleural fluid may provide instant relief; however, some patients may not respond. Unfortunately, the reaccumulation rate after thoracentesis alone is nearly 100% at 1 month.27 Traditionally, a blind approach was incorporated. Bedside ultrasound scanning makes this procedure much simpler and safer. If thoracentesis is performed for the first presentation of pleural effusion, the fluid should be sent for cytologic study because it may prove useful diagnostically. In general, unless a pleural effusion must be tapped for diagnostic purposes or to provide symptomatic relief, no need exists to tap the effusion in the ED. A chest radiograph should be performed at the completion of the procedure, to ensure that pneumothorax has not developed. More definitive treatment of the pleural effusion should be coordinated by the patient’s oncologist and will be tailored based on the patient’s prognosis, severity of symptoms, and type of malignant disease. Multiple treatment options exist, including supplemental oxygen, radiation therapy, chemotherapy, chemical pleurodesis, and long-term indwelling pleural catheter placement.

**Emergency Side Effects of Oncology Treatment**

Although some chemotherapeutic agents have unique side effects (Table 201.4), a few side effects are more universal. Bone marrow depression is a very common side effect of most agents. Nausea, vomiting, diarrhea, and mucositis are also quite common. The severity of these symptoms varies, depending on the particular chemotherapy agent.

**Global Issues**

**PAIN**

Pain in the oncology patient may represent an acute process, the progression of disease, or inadequate outpatient treatment. In a survey of physicians directly involved in cancer care (oncologists, hematologists, surgeons, and radiation therapists), 86% believed that most of their patients with cancer-related pain were being undermedicated, and 76% reported performing poor pain assessments for their patients. After potentially dangerous or reversible causes of pain have been ruled out and the patient’s pain is under control, usually in response to high doses of intravenous narcotics, a plan for outpatient pain control should be created with the patient and

</table>
in consultation with the patient’s oncologist. Oncologists tend to use an escalating approach to outpatient pain management, starting with nonsteroidal antiinflammatory drugs, then weaker opioids (e.g., codeine), and finally stronger opioids (e.g., morphine, fentanyl). Some physicians question this escalating approach, especially in advanced cancer, and instead start with small doses of stronger opioids and titrate upward as needed. Because the pain in patients with cancer is ongoing, pain medication with longer half-lives or continuous action, such as very-long-acting oral opioids or a transdermal opiate patch, is preferred. Additional short-acting medications should be provided for breakthrough pain; breakthrough dosing often needs to be 10% to 20% of the patient’s 24-hour total opiate dose. A new or escalating-dose opioid prescription should be accompanied by a prescription for a laxative because constipation is the most common side effect of opioid therapy.

### NAUSEA AND VOMITING

Nausea and vomiting, of all the side effects of chemotherapy, are often considered the worst adverse effects. Occasionally, nausea and vomiting can be severe enough to cause patients to discontinue their treatment. Poor antiemetic control with previous chemotherapy, female sex, low alcohol intake, and younger age are all associated with a higher risk of emesis after chemotherapy.\(^\text{29}\) In an effort to reduce the risk of emesis and to increase the tolerability of the treatment, chemotherapy regimens usually include an antiemetic drug. Chemotherapeutic agents with the highest emetogenic potential are listed in Box 201.2.\(^\text{30}\)

Conversely, nausea and vomiting can be the initial symptoms of a potentially life-threatening issue. Nausea or vomiting can be the first sign of a neurologic condition (e.g., increase in central nervous system pressure, brain metastasis, intracranial bleeding), a gastroenterologic disorder (e.g., bowel obstruction), or even a metabolic problem (e.g., hypercalcemia).

Patients who complain of nausea or vomiting in the ED should be treated promptly with a strong antiemetic and appropriate hydration. Serotonin receptor antagonists (e.g., ondansetron, granisetron) are among the most commonly used antiemetics for patients with cancer. Other commonly used antiemetics in this patient population include phenothiazines (e.g., prochlorperazine), benzamides (e.g., metoclopramide), and corticosteroids (e.g., dexamethasone), and benzodiazepines (e.g., lorazepam).

### MUCOSITIS

Mucositis is inflammation and ulceration of the mucous membranes, and it occurs in up to 58% of patients with cancer, depending on their diagnosis.\(^\text{31}\) Mucositis most commonly manifests in the mouth, but it can occur anywhere in the gastrointestinal, genitourinary, or respiratory tracts. Because mucositis is a breakdown of the normal integrity of mucous membranes, it is associated with an increased risk of infection. Oral mucositis is a side effect of chemotherapy or radiation, or it can result from certain cancers, such as oral cancers.
Patients who present to the ED with oral mucositis should be given proper pain control, which may include the use of opiates. Any secondary infections, such as oral candidiasis or herpes simplex, should be treated. A bland, soft diet is recommended, as well as ice chips or other cold products to keep the oral mucosa moist. Special attention to oral hygiene is essential for at-risk patients with cancer, including the use of a soft toothbrush, frequent saline or baking soda rinses, prophylactic anticandidal rinses (e.g., nystatin), and adequate general nutrition. Optimal mucositis treatment is still in question and requires further research. Protocols vary at different institutions. A 2010 Cochrane systematic review did not find any high-level evidence-based treatment options. Although not an ED option, low-level laser therapy was the only potentially useful intervention found in two or more clinical trials.

CARDIAC TAMPOONADE

EPIDEMIOLOGY

Malignant cardiac involvement is common, occurring in 11% to 12% of patients with cancer. Of these patients, three fourths have epicardial involvement, and one third of these patients have a pericardial effusion. The most common malignant primary tumor that progresses to involve the pericardium is lung cancer. Breast cancer, gastrointestinal cancers, melanoma, sarcoma, lymphoma, and leukemia account for most other cases. These tumors invade the pericardium through direct or metastatic spread. Less commonly, malignant primary pericardial tumors such as mesothelioma and sarcoma or benign tumors such as angioma, fibroma, or teratoma may occur. In a study conducted from 1996 to 2005, malignant disease was the primary cause of medical cardiac tamponade (65%), followed by unknown causes (10%), viral disease (10%), and anticoagulant medication–related intrapericardial bleeding (3%).

PATHOPHYSIOLOGY

The pericardium is a fibroelastic sac surrounding the heart that normally contains a thin layer of fluid. When a larger amount of fluid accumulates and exceeds the elastic limit of the pericardium, the heart begins to compete for the now fixed amount of intrapericardial space. As more fluid accumulates, the cardiac chambers become compressed, and diastolic compliance lessens.

Throughout this process, the decline in intrathoracic pressure associated with inspiration continues to be transmitted through the pericardium to the heart. Thus, venous return to the heart is still increased with inspiration. However, the free wall of the right ventricle cannot expand to accommodate this increased volume, thus leading the intraventricular septum to bow to the left. The result is decreased left ventricular filling during inspiration. When the size of the effusion progresses further, total venous return diminishes, and cardiac output and blood pressure deteriorate.

Cardiac tamponade is generally classified as acute or subacute. In acute cardiac tamponade, the relatively stiff pericardium can become rapidly filled with blood that causes tamponade with only a small effusion. This generally occurs...
in the setting of trauma, myocardial or aortic rupture, or invasive medical interventions. In subacute cardiac tamponade, a much larger effusion accumulates slowly and allows the pericardium to stretch over time. This type of tamponade occurs most commonly in the setting of malignant disease or renal failure, and it may not occur until the amount of pericardial fluid reaches 2 L or more. In either setting, very little additional fluid may cause cardiac tamponade once the limits of pericardial elasticity have been reached.

**PRESENTING SIGNS AND SYMPTOMS**

**CLASSIC**

Cardiac tamponade is a physiologic continuum, from mild to severe. Classically, patients present with tachypnea and dysnea on exertion. As the disease progresses, patients may have shortness of breath at rest, peripheral edema, or orthopnea. Patients with severe disease may be obtunded on presentation, thus obscuring the diagnosis of cardiac tamponade. A history of malignant disease or symptoms and signs of malignant disease such as weight loss, fatigue, or anorexia may help to guide the clinician toward a diagnosis of malignant pericardial effusion.

**PHYSICAL FINDINGS**

Patients with pericardial tamponade most commonly present with shortness of breath, hypotension, and often with clear lungs. Unfortunately, physical examination holds little value for diagnosing the presence of a pericardial effusion. However, as a malignant effusion becomes large enough to cause cardiac tamponade, some distinct physical findings may become evident. The Beck triad, first described in 1935, consists of increased jugular venous pressure, hypotension, and muffled heart sounds. However, this triad is most useful in acute cardiac tamponade, and it may be uncommon or difficult to assess in patients with atrumatic cardiac tamponade.

Sinus tachycardia is seen in most patients with cardiac tamponade. This physiologic response allows for maintenance of cardiac output despite decreased cardiac filling volumes. Patients may present with slightly lower heart rates if they are taking beta-blocking medications or if they suffer from hypothyroidism. Significant tamponade also manifests with absolute or relative hypotension. Patients with early tamponade may present with normotension or even hypertension, especially if they have preexisting hypertension.

*Pulsus paradoxus* is defined as a drop of more than 10 mm Hg in systolic blood pressure during normal inspiration. Most patients with moderate to severe cardiac tamponade have pulsus paradoxus, which is often palpable in the peripheral arteries. As cardiac output drops, however, pulsus paradoxus may be difficult to measure without invasive monitoring. Pulsus paradoxus results when the effusion limits expansion of the free wall of the right ventricle as venous return increases during inspiration. The right ventricle is then forced to expand by bulging the intraventricular septum into the left ventricle, thus leading to greatly reduced filling and stroke volume during inspiration.

To quantify pulsus paradoxus noninvasively, a sphygmomanometer is used in the standard fashion. The cuff is inflated to more than the systolic blood pressure and then is slowly deflated until the first Korotkoff sounds are audible only during exhalation. This condition is typified by hearing Korotkoff sounds for several beats during exhalation, followed by silence during inspiration, and then followed by Korotkoff sounds for several beats during exhalation. The pressure is noted on the sphygmomanometer at this point, and slow deflation is continued until all beats are audible. The amount of pulsus paradoxus is determined by subtracting the pressure at which all beats are heard from the pressure at which beats were heard only during exhalation.

Multiple conditions may alter the physiology of cardiac tamponade and may cause pulsus paradoxus to be absent. The most common conditions are elevated left ventricular diastolic pressures and increased heart rate. Other conditions include severe hypotension, irregular rhythm, atrial septal defect, regional cardiac tamponade, and severe aortic regurgitation.

**MEDICAL DECISION MAKING AND DIAGNOSTIC TESTING**

**ELECTROCARDIOGRAPHY**

The electrocardiogram is abnormal in most, but not all, patients with pericardial effusion. The most common findings are nonspecific ST-segment and T-wave abnormalities and sinus tachycardia. The electrocardiogram may mimic that seen in acute pericarditis.

Low QRS voltage may be a sign of a large pericardial effusion, but it is more likely to be associated with tamponade physiology. In one small study, Bruch et al. studied 43 patients with a pericardial effusion. Of those patients, 14 of 23 with tamponade demonstrated low-voltage QRS complexes, as opposed to none of the 23 patients with effusion but without tamponade (Fig. 202.1). Electrical alternans (Fig. 202.2), demonstrated as beat-to-beat alterations in the amplitude of the QRS complex, is relatively specific but not very sensitive for cardiac tamponade. Electrical alternans may also rarely occur in patients with very large effusions without tamponade. Electrical alternans is caused by swinging of the heart in the pericardial effusion, and it generally disappears after removal of even modest amounts of pericardial fluid.

**CHEST RADIOGRAPHY**

The typical finding on chest radiograph is an enlarged cardiac silhouette (the “water bottle”-shaped heart), as seen in Figure 202.3. In most cases, the lung fields are clear unless preexisting lung disease (e.g., malignant disease) is present. Cardiac tamponade may manifest without an enlarged cardiac silhouette if a small, rapidly accumulating effusion is the cause.

**ECHOCARDIOGRAPHY AND EMERGENCY MEDICINE BEDSIDE ULTRASOUND**

Echocardiography and emergency medicine bedside ultrasound play crucial roles in the diagnosis of cardiac tamponade. The first steps are to suspect a problem and to perform a screening cardiac ultrasound examination (Fig. 202.4).

Echocardiographic findings indicative of cardiac tamponade include the presence of pericardial fluid with accompanying diastolic collapse of the right atrium and right ventricle. During atrial relaxation at the end of diastole, pericardial pressure is maximal, whereas right atrial volume is minimal. This situation results in right atrial collapse that, if lasting more than one third of the cardiac cycle, is sensitive and

pericardial drainage if the patient’s clinical condition should
deteriorate.

Patients with severe hemodynamic compromise require
immediate removal of pericardial fluid. Pericardiocentesis
should be performed to remove as much of the pericardial
effusion as possible. Percutaneous aspiration of even 50 to
100 mL has been demonstrated to reverse cardiac tamponade
physiology temporarily.

Pericardiocentesis may be performed under electrocardiog-
graphic or echocardiographic guidance. Echocardiographic
guidance is preferred when available, because it allows greater
precision of procedure direction and needle angle. Placement
of an indwelling catheter is advisable, to prevent reaccumula-
tion of fluid. The technique used for pericardiocentesis can be
found in the “Tips and Tricks” box. Fluid obtained from peri-
cardiocentesis should be sent for Gram stain, culture, acid-fast
stain and culture, cytologic study, carcinoembryonic antigen
determination, and polymerase chain reaction evaluation.

Complications of pericardiocentesis are listed in Box 202.1.

specific for cardiac tamponade. Right ventricular diastolic
collapse occurs early in diastole when ventricular volume is
minimal. Left atrial collapse is less common, but it is also
very specific for cardiac tamponade. Collapse of the left
ventricle is uncommon because of its greater muscular
thickness.

As discussed earlier, left- and right-sided volumes vary
with the respiratory cycle. During inspiration, the atrial and
ventricular septa bulge to the left. During expiration, the atrial
and ventricular septa bulge rightward.

**TREATMENT**

Patients with mild hemodynamic compromise require urgent
drainage of pericardial fluid. If the patient is sufficiently
stable, cardiology and cardiothoracic surgery consultation
may be appropriate to decide whether emergency catheter
drainage or surgical creation of a pericardial window is the
most appropriate therapy. In such cases, the emergency physi-
cian (EP) should be prepared to perform emergency

**DISPOSITION AND PROGNOSIS**

Patients with cardiac tamponade are admitted to the hospital,
typically in a cardiac care or intensive care unit (see the “Pri-
ority Actions” box). Emergency referral to cardiology for a
pericardial window procedure is determined if the patient is hemodynamically stable for the procedure. Documenting the hemodynamic instability and emergency intervention is important (see the “Documentation” box). Initial in-hospital mortality is high for patients with malignant effusion and pericardial tamponade; the median survival is 150 days, and the 1-year mortality rate is 76.5%. This mortality results jointly from the underlying cancer and the cardiovascular compromise.2

• Vital signs, examination findings, and diagnostics supporting hemodynamic instability and cardiac tamponade physiology
• Informed consent for the emergency pericardiocentesis
• Postintervention assessment of vital signs, examination findings, or diagnostics to support therapeutic reversal of tamponade and improved patient clinical condition
• Code status to support the patient’s wishes given the underlying cancer history and invasiveness of the procedure

SUPERIOR VENA CAVA SYNDROME

EPIDEMIOLOGY

The superior vena cava (SVC) may become obstructed either acutely or subacutely, thus causing SVC syndrome. This condition may be caused by extrinsic mass, infiltration of the SVC by contiguous pathologic processes, or thrombosis. In the preantibiotic era, syphilitic aortic aneurysms, fibrosing mediastinitis, and complications of untreated infections were the most common causes of SVC syndrome. Currently, malignant disease is the cause of SVC syndrome in 85% of cases. Bronchogenic carcinomas account for most cases, and small cell and squamous cell carcinomas are far the most common causes. Although lung cancer is the leading cause of SVC syndrome, the overall incidence of SVC syndrome in patients with lung cancer is low, at 2% to 4%. The next most common malignant cause of the SVC syndrome is non-Hodgkin lymphoma because of its frequent presentation as a mediastinal mass. Metastatic cancers account for a small proportion of cases of SVC syndrome. Patients with SVC syndrome rarely experience immediately life-threatening complications in the absence of concurrent central airway obstruction.6,7

Benign causes of SVC syndrome account for 10% to 15% of cases. In the patient with cancer, the most common benign cause is the presence of indwelling vascular devices such as hyperalimentation lines and chemotherapy ports or lines, which induce thrombosis of the SVC. Other causes include fibrosing mediastinitis resulting from histoplasmosis, as well as other infections.

PATHOPHYSIOLOGY

SVC syndrome is caused by one of several mechanisms. The first is direct compression by tumor or by enlarging lymph nodes (from inflammation or metastatic disease). The second is direct invasion of the SVC by tumor or other pathologic processes. The third is obstruction of the SVC by thrombus. Thrombus may additionally occur in up to 50% of patients with one of the other causes of SVC syndrome, and it may account for some treatment failures when therapy is directed at the underlying malignant disease.8 With compression of the

TIPS AND TRICKS

Technique for Pericardiocentesis Using Ultrasound Guidance

- Using bedside ultrasound, locate the ideal site of skin puncture where the largest fluid collection lies closest to the skin surface. This site is usually located on the left anterior chest wall. The clinician can choose either to mark the skin or to use the ultrasound device with a sterile sheath for dynamic guidance at this point.
- Prepare the skin in sterile fashion, and anesthetize the skin if time permits.
- Attach a 20-mL syringe to an 18-gauge spinal needle.
- Insert the needle at the site and trajectory determined by bedside ultrasonography. Take care to avoid the neurovascular bundle at the lower rib border and the internal mammary artery, which lies 3 to 5 cm lateral to the sternal border.
- Gently aspirate as the needle is advanced until fluid is obtained.
- Aspirate as much fluid as possible using the three-way stopcock.
- Alternately, use an over-the-needle catheter or the Seldinger technique if prolonged drainage is necessary. The Seldinger technique is performed using the same methods as outlined, but the clinician may use a thin-walled 18-gauge needle to pass a guidewire, followed by a catheter (e.g., a pigtail catheter) that may be left in place.

PRIORITY ACTIONS

- Consider malignant pericardial effusion in patients with a history of cancer who have tachypnea and dyspnea on exertion.
- Determine whether the patient has cardiac tamponade physiology by physical examination (i.e., Beck triad, pulsum paradoxus) or diagnostic evaluation (i.e., emergency bedside ultrasound).
- Perform an emergency pericardiocentesis or refer to cardiology for a pericardial window, based on hemodynamic instability.
- Assess for postprocedure reversal of tamponade physiology and for complications.
- Admit to a cardiac care or intensive care unit so that vital sign monitoring and follow-up diagnostics can be performed.
SVC, the patient has increased resistance to venous blood flow, which is diverted through collateral venous networks.

**PRESENTING SIGNS AND SYMPTOMS**

The physical examination of the patient with SVC syndrome is often diagnostic. Most patients have facial edema or dilation of chest wall or neck veins. Some patients have cyanosis, arm edema, or plethora. A patient with the SVC syndrome who does not have visible upper body venous dilation is rare. An indwelling central venous device may be a clue to the diagnosis in thrombotic causes of SVC syndrome.

Dyspnea, one of the most common symptoms of SVC syndrome, occurs in more than half of patients. Patients may complain of fullness or swelling of the face, trunk, or upper extremities that may be exacerbated by positional changes such as bending over or lying down. Contrary to previous beliefs, catastrophic neurologic events appear to be quite rare. Findings of cerebral edema, laryngeal edema or upper airway stridor, or hemodynamic compromise represent the greatest emergencies.

**MEDICAL DECISION MAKING AND DIAGNOSTIC TESTING**

The initial test of choice when SVC syndrome is suspected is chest plain film radiography. Most of these radiographs are abnormal; one series found 84% of films to be abnormal. The most common abnormal findings were mediastinal widening in 64% (Fig. 202.5) and pleural effusion in 26%. A mass may also be seen in the superior mediastinum, right hilum or perihilum, or right upper lobe. Less commonly, right upper lobe collapse or rib notching may be apparent. However, a normal chest radiograph does not rule out the possibility of SVC syndrome.

The next test is a contrast-enhanced computed tomography (CT) scan (Fig. 202.6). CT defines the level and extent of blockage, provides detail on the amount of collateral flow, and is often able to identify the cause of obstruction. The presence of collateral vessels with compression of the SVC on CT is a reliable indicator of SVC syndrome, with a sensitivity of 96% and a specificity of 92%.

**TREATMENT**

Rarely, SVC syndrome requires emergency care, as in the case of cerebral edema, airway obstruction, or hemodynamic compromise. In these situations, airway and vascular support and a specialist to assist in managing the obstruction are required. More commonly, symptomatic therapy should be instituted, including elevation of the head of the bed, oxygen, and bed rest. Diuretics and steroids have been used without clear evidence of efficacy. Anticoagulation may be of benefit in patients with thrombotic causes, after the origin is determined. Endovascular stenting has been successful in symptomatic improvement, and it has been steadily gaining favor as a treatment modality.

**DISPOSITION AND PROGNOSIS**

All patients diagnosed with the SVC syndrome should be admitted to the hospital (see the “Priority Actions” box). The

---

**PRIORITY ACTIONS**

- Diagnose the SVC syndrome in a patient with lung cancer or lymphoma with head or neck swelling, engorged upper extremity veins, plethora, or dyspnea.
- Determine whether the patient has any emergency obstructive SVC syndrome findings of cerebral edema, airway obstruction, or hemodynamic compromise, and provide supportive measures and specialist consultation on an emergency basis.

SVC, Superior vena cava.
level of care should be chosen based on the clinical stability of the patient. Oncology specialists should be consulted to help begin the work-up necessary to establish a histologic diagnosis, if one is not already known.

Survival of patients with the SVC syndrome depends on the underlying diagnosis and the treatments chosen. The median survival is 6 months, but it may differ considerably based on the type of malignant disease.

Neurologic Oncologic Emergencies

PERSPECTIVE

The primary neurologic oncologic emergencies encountered in the ED can be divided into those that affect the central nervous system (CNS), including altered mental status, increased intracranial pressure (ICP), and seizures from brain tumors or metastatic lesions, and those that affect the peripheral nervous system, such as epidural spinal cord compression (ESCC). Generally, these emergencies involve acute to subacute presentations and result from mechanical obstruction of normal neurologic function. Patient morbidity and mortality can be improved by early recognition and management directed at relieving the neurologic obstruction or preventing secondary injury.

CENTRAL NERVOUS SYSTEM EMERGENCIES

EPIDEMIOLOGY

The most important CNS manifestations include altered mental status, elevated ICP, and seizures. Brain tumors represent a diverse group of neoplasms that can originate primarily from the CNS or metastatically through hematogenous spread from distant organs.

Although brain tumors account for only 2% of all tumors, they have significant sequelae. The 5-year survival rate of patients of all ages and all races who have malignant brain tumors is 33%; for children less than 14 years old, it is 62%; and for adults 65 years or older, it is 4.9%.12 In children, brain tumors are the most common solid malignant tumors and the second leading cause of cancer death after leukemia. Box 202.2 illustrates the differences in primary tumor types between adults and pediatric patients.

Brain metastases are more common than primary tumors in adults and account for more than half of all intracranial brain tumors. In adults with systemic malignant diseases, brain metastases occur in 10% to 30% of patients. The most common primary tumors responsible for brain metastases in adults are carcinomas, and they include lung cancer, renal cell cancer, melanoma, breast cancer, and colorectal cancer. In children with systemic malignant diseases, brain metastases occur in 6% to 10% of patients. The most common primary tumors responsible for brain metastases in children are sarcomas, neuroblastomas, and germ cell tumors.

In general, a slight male predominance is seen in the incidence of malignant brain tumor. Whites have the highest incidence, with a descending incidence in Latinos and African Americans, and the lowest incidence in Native Americans and Asian Americans.12 The rising incidence of brain tumors in industrialized countries is thought to be mostly a result of environmental exposures and improved detection using diagnostic imaging.

Although cancers typically are indolent in their evolution, the neurologic manifestations may be acute or chronic, and they may be local or distant from the primary source. Rapid diagnosis and treatment are imperative to prevent irreversible damage, primarily from cerebral hypoxia, inflammation, or swelling, which can have catastrophic consequences. The long-term prognosis of patients with cancer and significant neurologic complications is poor, and recurrence of illness is common despite optimal management.

PATHOPHYSIOLOGY

The pathogenesis of tumor-related neurologic dysfunction involves disruption of the blood-brain barrier leading to vasogenic edema. This condition is caused primarily by factors that increase the permeability of the tumor vessels (vascular endothelial growth factor, glutamate, and leukotrienes) and by the absence of tight endothelial cell junctions in tumor blood vessels. This process culminates in leakage of protein-rich
fluid into the extracellular space, predominantly in the white matter of the brain. When this peritumoral edema begins to accumulate, the synaptic transmission can be disrupted and thus can lead to altered neuronal excitability and neurologic sequelae (Fig. 202.7). Vasogenic edema is what causes patients to suffer from headaches, nausea or vomiting, seizures, cognitive dysfunction, focal neurologic deficits, encephalopathy, or increased ICP leading to syncope or fatal herniation. Intratumoral hemorrhage, obstructive hydrocephalus, and tumor embolization can also have tumor-related consequences, but these entities are much less common than vasogenic edema.

Brain metastases arrive through hematogenous spread. They are usually located in two places. The first is directly at the junction of the gray and white matter, where smaller vessels begin to trap tumor cells. The second is at terminal "watershed areas" of arterial circulation. Metastases distribute according to weight and blood flow and are seen in the cerebral hemispheres (80%), in the cerebellum (15%), and in the brainstem (5%). Pelvic (prostate and uterine) and gastrointestinal tumors commonly metastasize to the posterior fossa, whereas small cell lung carcinoma distributes equally through all regions of the brain.

**PRESENTING SIGNS AND SYMPTOMS**

A classic presentation to the ED for brain metastasis is a patient with known cancer who has a sudden onset of a neurologic deficit or change in mental status, syncope, or seizure. Patients with primary or metastatic disease can present with either generalized or focal signs or symptoms. Generalized symptoms include headaches, nausea or vomiting, generalized seizures, cognitive dysfunction, and loss of consciousness. Focal symptoms include weakness, sensory loss, aphasia, focal seizures, and visual spatial dysfunction.

Headache is the most common symptom of brain tumor, and headaches occur in approximately 40% to 50% of patients with primary or metastatic brain tumors. In one retrospective review, headaches were described variably, but most were described as tension-type headaches. The patients described the headaches as bifrontal and worsening ipsilateral to the lesion.13 Tumor-related headaches were differentiated from tension headaches by complaints of nausea and vomiting or especially by worsening of the headache with changes in body positioning that increased ICP (i.e., leaning forward). Worsening of the headache typically occurred following maneuvers that increase intrathoracic pressure, such as coughing, sneezing, or the Valsalva maneuver.

Tumor-related headaches tend to be worse at night because of small increases in the partial pressure of carbon dioxide, recumbency, and decreased cerebral venous return. Headaches related to increased ICP are thought to be mediated by the pain fibers of cranial nerve V in the dura and blood vessels. Headaches associated with increased ICP can be the result of large mass lesions or of restriction of cerebrospinal fluid outflow causing hydrocephalus. Classically, increased ICP is manifested by the classic triad of headache, nausea and vomiting, and papilledema. Thus, a careful ophthalmologic examination is requisite for all patients with complaints of headache.

Seizure represents the most common presenting symptom of gliomas and cerebral metastases. In these tumor types, one study showed that seizure was the initial complaint in

---

**Fig. 202.7** Pathophysiology of vasogenic edema. A, Tumor vessel with factors that increase vascular permeability. VEGF, Vascular endothelial growth factor. B, Protein-rich fluid leaking into extracellular spaces. C, Disruption of synaptic transmission. D, Neurologic sequelae.
Patients who present with seizure activity usually have smaller primary tumors or fewer metastatic lesions in the brain compared with other presenting symptoms, because the seizure leads to earlier diagnostic imaging and diagnosis. Seizures can be generalized or focal, depending on the location in the brain of the tumor. Frontal lobe tumors may cause tonic-clonic movements in an extremity, and occipital lobe tumors may cause visual disturbances. Temporal lobe seizures may cause abrupt personality changes. Patients with a history of tumor-related seizures commonly present in a similar fashion on each visit, with or without a prodromal phase followed by a postictal period. If the seizures are generalized, the patient will be fatigued and sleepy; if the seizures are focal, however, the patient may have Todd paralysis.

Acute mental status change describes a deficit in cognitive function and is a presenting complaint in approximately 30% to 35% of patients with brain metastases. Cognitive dysfunction includes memory problems and mood or personality changes. Patients commonly present with fatigue, low energy, increased urge to sleep, and apathy toward daily activities.

**TREATMENT**

The main goals of treatment for neurologic manifestations of oncologic emergencies are to preserve and maintain cerebral oxygenation and perfusion, to decrease inflammation and swelling, and to identify and correct the underlying condition. In the severely neurologically depressed patient with a declining Glasgow coma scale and an inability to protect the airway, rapid-sequence endotracheal intubation should be performed, with supplemental oxygen administered to prevent cerebral hypoxia. Before intubation, care should be taken to prevent a rise in ICP, and appropriate choices for sedation and paralytic agents should be used.

Pretreatment with 1 to 1.5 mg/kg of lidocaine to blunt the rise in ICP from intubation has limited supporting evidence, but it can be used as an adjunct. Etomidate is the best choice for sedation, at a dose of 0.3 mg/kg, and it induces general anesthesia without raising ICP or dropping blood pressure.
Another agent for sedation, propofol, at a dose of 2 mg/kg, induces general anesthesia without raising ICP with the advantage of rapid onset of action and a short half-life. A defasciculating dose of a nondepolarizing agent (e.g., 0.01 mg/kg of vecuronium) may help to blunt the fasciculations caused by succinylcholine (1.5 mg/kg).

Diagnostic neuroimaging must be performed immediately following stabilization to ascertain the underlying cause of neurologic dysfunction. Once the patient is stabilized and the brain is adequately oxygenated, secondary treatments must be performed to protect the brain from further injury such as increasing edema or herniation.

Corticosteroids, specifically dexamethasone, help to reduce the inflammatory response by decreasing the permeability of tumor capillaries and by clearing edema through transport of fluid into the ventricular system. Dexamethasone is the standard agent of choice because of its antiinflammatory effects and its relative lack of mineralocorticoid activity, which may cause fluid retention. The initial dose is typically a 10-mg loading dose. If the drug is given orally, absorption is completed within 30 minutes. Tumor-related weakness is very responsive to dexamethasone treatment.

Reduction of ICP and improvement of neurologic symptoms usually begin within hours. The permeability of the blood-brain barrier has been found to improve within 6 hours, and changes in MRI demonstrating decreased edema have been shown within 2 to 3 days. The long-term side effects of corticosteroid use include gastrointestinal complications, steroid myopathy, and opportunistic infection.

If steroids alone cannot effect adequate reduction of ICP, increasing ICP can evolve into a medical emergency leading to herniation. The neurologic intensive care specialist will consider placement of a ventriculostomy to monitor the ICP and to drain cerebrospinal fluid to reduce ICP. The goal of ICP monitoring and treatment should be to keep ICP to less than 20 mm Hg and cerebral perfusion pressure (CPP) between 60 and 75 mm Hg. In the patient who has required intubation, the head of the bed should be elevated 30 degrees to decrease ICP.

Osmotic agents (e.g., mannitol, at a dose of 1 g/kg) reduce ICP by 50% in 30 minutes, peak after 90 minutes, and last 4 hours. Loop diuretics (e.g., furosemide, 1 mg/kg) also decrease ICP without increasing serum osmolality. The use of mannitol or diuretics can be discussed with the neurologic intensive care specialist. Hyperventilation to reduce ICP is controversial; if it is performed after discussion with the neurologic intensive care specialist, however, all efforts should be made to keep the partial pressure of carbon dioxide between 30 and 35 mm Hg. Sedation should also be continued to reduce metabolic demand.

Blood pressure control should attempt to maintain CPP higher than 60 mm Hg, because systemic hypotension and resultant low CPP actually increase ICP. Pressors can be used safely without further increasing ICP if the blood pressure becomes too low. Hypertension should generally be treated only when CPP is higher than 120 mm Hg and ICP is higher than 20 mm Hg, to prevent further damage. The patient should be kept euvoletic with 0.9% normal saline to ensure that no
hypotension from hypovolemia or hydrocephalus from hypervolemia occurs. The patient should also be kept in the normal osmolality range (295 to 305 mOsm); hypotension may be managed with hypertonic saline after discussion with the intensive care specialist because its use is controversial. Euglycemia (80 to 120 mg/dL) should be maintained for metabolic needs.

Antiemetic medications should be used so that vomiting does not increase ICP. Barbiturate therapy can be considered to reduce ICP based on the ability of these drugs to reduce brain metabolism and cerebral blood flow. Pentobarbital is often used, with a loading dose of 5 to 20 mg/kg as a bolus, followed by 1 to 4 mg/kg/hour. Treatment should be assessed based on ICP, CPP, and the presence of unacceptable side effects such as hypotension. Continuous electroencephalographic monitoring is generally used. Therapeutic hypothermia has not been reliably studied in increased ICP secondary to oncologic emergencies and is not currently standard management. Treatment alternatives to assist in the care of acute vasogenic edema are listed in the “Tips and Tricks” box.

The main goals of treatment in tumor-related seizures are to ensure adequate oxygenation and perfusion and to stop prolonged seizures or evolving status epilepticus. In addition to supplemental oxygenation and steps to ensure that the patient is not injured, the initial choice of medication is a benzodiazepine such as lorazepam (2 to 4 mg intravenous loading dose). If the seizure is refractory, and monotherapy with escalating doses of benzodiazepines is not working, consider the addition of phenobarbital (20 mg/kg intravenous loading dose) or phenytoin (18 mg/kg intravenous loading dose).

Prophylactic anticonvulsants are commonly considered in patients with diagnosed brain tumors but who have not had a seizure. Prophylactic anticonvulsants were reviewed by the Quality Standards Subcommittee of the American Academy of Neurology, and the summary recommendation stated that prophylaxis did not affect the frequency of subsequent seizures and should not be used in patients with either primary or metastatic brain tumors. Thus, the subcommittee believed the 5% to 25% subsequent seizure risk in brain tumors was outweighed by the deleterious interactions of anticonvulsants with cytotoxic drugs and corticosteroids. In postoperative seizure, the subcommittee recommended that anticonvulsants should be tapered and discontinued after the first postoperative week in patients who have not had a seizure, particularly in patients who are medically stable and are experiencing anticonvulsant-related side effects.

### TIPS AND TRICKS

Treatment Alternatives for Patients with Acute Vasogenic Edema

- **Corticosteroids**
  - Dexamethasone (10-mg loading dose)
- **Osmotic agents or diuretics**
  - Consider mannitol (1 g/kg).
  - Consider furosemide (1 mg/kg).
- **Antiemetics (phenothiazine of choice or ondansetron for refractory vomiting)**
- **Euvolemia (0.9% normal saline solution)**
- **Euglycemia (80 to 120 mg/dL)**
- **Normal osmolality (295 to 305 mOsm)**
  - Consider hypertonic saline after discussion with specialist.
- **Blood pressure control (CPP > 60 mm Hg and CPP < 120 mm Hg when ICP > 20 mm Hg)**
  - Consider pressors for hypotension.
  - Consider calcium channel blockers or beta-blocking agents for hypertension.
- **Ensure airway protection with intubation if necessary.**
- **Consider pretreatment with an agent to blunt increased ICP** (e.g., 1.5 mg/kg lidocaine).
- **Choose a sedative agent that does not increase ICP** (e.g., etomidate 0.3 mg/kg or propofol 2 mg/kg).
- **Consider a defasciculating dose of a nondepolarizing agent before a depolarizing agent** (e.g., 0.01 mg/kg vecuronium before 1.5 mg/kg succinylcholine).
- **Elevate the head of the bed to 30 degrees.**
- **Consider hyperventilation after discussion with a specialist** (ensure 
  \[P_{CO_2}\] 30 to 35 mm Hg).
- **Consider antiseizure medication or barbiturate therapy** (i.e., lorazepam, 2–to 5-mg bolus, or pentobarbital, 5-to 20-mg/kg bolus, then 1 to 4 mg/kg/hour).

CPP: Cerebral perfusion pressure; ICP: intracranial pressure; \(P_{CO_2}\): partial pressure of carbon dioxide.

### DISPOSITION AND PROGNOSIS

Once stabilized, patients presenting with neurologic complications of cancer require admission to the hospital (priority actions for the management of cerebral oncologic emergencies are listed in the “Priority Actions” box). Patients with significantly depressed neurologic function require intubation, neuroprotective interventions, and intensive monitored care by a neurologic intensive care specialist. Patients who are awake, hemodynamically stable, and protecting their airway...
require admission to a general unit with neurology and medical oncology evaluation. Careful documentation of change in neurologic status is important (see the “Documentation” box). The prognosis of patients with CNS oncologic emergencies is generally poor.

**EPIDEMIOLOGY**

Neoplastic ESCC is a common complication of metastatic cancer that has been documented to occur in 5% of patients with cancer. The most widely accepted definition of ESCC includes any radiographic indentation of the thecal sac. Although the cauda equina is not technically considered part of the spinal cord, the pathophysiology of compression of the cauda equina is the same as that of the spinal cord. Thus, compression of the thecal sac by malignant disease at this level is also referred to as ESCC.

The most common tumors are prostate, breast, and lung cancers (each accounting for 15% to 20% of all cases), which tend to metastasize to the vertebral column. Other important tumors are renal cell carcinoma, multiple myeloma, non-Hodgkin lymphoma, and plasmacytoma, which make up most of the remaining cases. In children, the most common causes are sarcomas, neuroblastomas, Hodgkin lymphoma, Wilms tumor, and germ cell tumors. The most common vertebral levels of involvement for ESCC for all age groups are the thoracic spine (60% to 78%), followed by the lumbar spine (16% to 33%), followed by the cervical spine (4% to 15%); multiple levels are involved in up to 50% of patients. Delays in diagnosis and treatment remain common, and reports from multiple countries describe poor neurologic outcome in half or more of patients diagnosed with ESCC, including motor weakness, bladder dysfunction, and inability to ambulate.

**PATHOPHYSIOLOGY**

The most common method for hematogenous spread to the spinal column is by direct arterial embolization of tumor cells. The seeding of these cells creates a destructive and expansive mass in the vertebral body. As the vertebral body weakens, both the tumor and collapsed bony fragments place pressure on the epidural space and subsequently on the thecal sac that results in ESCC.

**PRESENTING SIGNS AND SYMPTOMS**

The most common presenting symptom of ESCC is back pain, which occurs in more than 80% of patients. In general, pain precedes the onset of neurologic symptoms by several weeks. The pain is generally slowly progressive, although abrupt worsening of pain may signal a pathologic compression fracture. The pain may worsen with recumbency, movement, or the Valsalva maneuver, or it may develop a radicular quality. The radicular pain may be bilateral, especially in thoracic lesions.

Motor weakness is present in most patients with ESCC at the time of diagnosis. When the cauda equina is compressed, the deep tendon reflexes may also be depressed. Laterally situated tumors may cause isolated motor radiculopathy or radiculopathy superimposed on bilateral lower extremity weakness. Weakness tends to be most pronounced in patients with thoracic lesions.

Sensory findings are present in more than half the patients with ESCC. Patients often report ascending numbness or paresthesias. When a sensory level is present, it is generally several levels below the actual level of spinal cord compression. Cauda equina lesions result in saddle anesthesia, whereas higher lesions often spare these sacral dermatomes. Like motor symptoms, sensory symptoms can occur in a radicular pattern.

Bowel dysfunction and bladder dysfunction are often late findings, but these disorders are frequently present by the time

---

**RED FLAGS**

Malignant Epidural Spinal Cord Compression Cautions for the Physician

- Back pain in a patient with prostate, lung, or breast cancer
- Repeat patient visits for accelerating back pain with risk factors for cancer without a plan for diagnostic imaging
- Not including ESCC in the differential diagnosis of a patient with urinary retention with risk factors for cancer
- Assuming that the ESCC is limited to the lumbar spine
- Not documenting a thorough neurologic examination, including strength, sensation, rectal tone, or reflex testing, in a patient suspected of malignant ESCC
of diagnosis of ESCC. The most common presenting symptom is urinary retention, which may be potentiated by the use of narcotic analgesics for the back pain. Other signs and symptoms of myelopathy that may indicate ESCC include diminished proprioception, ataxia, spasticity, reflex hyperactivity, and autonomic dysfunction. The presenting signs and symptoms of ESCC are difficult to diagnose, and cautions for the physician are listed in the “Red Flags” box.

**MEDICAL DECISION MAKING AND DIAGNOSTIC TESTING**

Although plain radiography is easily accessible in the ED and is able to predict ESCC in most patients with an evident lesion, it is still generally inadequate. Between 10% and 17% of patients have ESCC without findings on plain radiography.16

MRI and myelography (or CT myelography) remain the cornerstones of diagnosis of ESCC. MRI holds several advantages in that it is accurate, reliable, noninvasive, and able to image the entire thecal sac regardless of whether myelographic block is present (Fig. 202.13).

In general, definitive imaging is necessary when ESCC is suspected. Imaging should be performed on an emergency basis in any patient with evidence of neurologic dysfunction suspected to be caused by ESCC. In patients with cancer who have new or worsening back pain without any evidence of neurologic dysfunction and a normal plain radiograph, it is probably reasonable to allow urgent outpatient definitive imaging.

**TREATMENT**

When epidural metastatic lesions are found in the investigation for ESCC, therapy is indicated for any patients who have not had prolonged paraplegia (more than several days). The cornerstones of therapy are corticosteroids, radiation therapy, and, in some cases, surgery.

The value of corticosteroids to relieve edema contributing to spinal cord compression is well documented. What remains controversial is the dosage of dexamethasone. Initial bolus doses of anywhere from 10 to 100 mg have been used, with no clear answer on the most appropriate dosage. Subsequent lower doses may be given orally as directed by the consultant specialist. Steroids should be given immediately, even before MRI scanning, if ESCC is strongly suspected or if ESCC is suspected and appropriate imaging will be delayed for any reason.

Neurosurgery should be consulted immediately for cases of ESCC. The consultant will weigh the neurologic status of the patient and clinical variables such as life expectancy to tailor a treatment plan for the patient including radiation therapy or surgery.

**DISPOSITION AND PROGNOSIS**

Patients with ESCC are admitted to the hospital, and they should have early ED consultation by a neurosurgeon (see the “Priority Actions” box). In general, the outcomes of patients following ESCC heavily depend on the neurologic status of the patient at the time of diagnosis, and documentation is very important (see the “Documentation” box). Although the median survival of patients diagnosed with ESCC is 6 months, the outcome is better in patients who are ambulatory at the time of diagnosis. Patients with lung cancer as the source of metastatic disease have poorer prognosis than those with breast or prostate cancer.

**DOCUMENTATION**

- Thorough neurologic examination, including motor, sensory, genitourinary (including rectal tone), and reflex testing
- Serial neurologic examinations to assess for a change in condition
- Time of neurologic consultant evaluation and recommendations and interventions
- Code status to support the patient’s wishes given the underlying cancer history and neurologic outcome

**PRIORITY ACTIONS**

- Consider ESCC in patients with a history of cancer with back pain and focal neurologic dysfunction.
- Treat with dexamethasone.
- Obtain prompt neurologic specialist input because preintervention neurologic function predicts the postintervention neurologic outcome.

ESCC, Epidural spinal cord compression.

White Blood Cell Disorders

Eric Goralnick

White blood cell disorders are the result of cell overproduction, underproduction, or dysfunction. Hematologic malignant diseases have variable initial presentations and significant associated complications. Rapid evaluation and intervention are essential to minimize morbidity and mortality in the immunocompromised patient.

EPIDEMIOLOGY

The National Cancer Institute estimated that approximately 137,260 new cases and 54,020 deaths from hematologic malignant diseases (leukemias, lymphomas, and plasma cell disorders) occurred in 2010. On January 1, 2007, approximately 908,512 men and women living in the United States had a history of hematologic malignant disease. In adults, non-Hodgkin lymphomas and chronic lymphocytic leukemia are the most common of these diseases. Of a total of 26,446 childhood cancers (age 1 to 19 years) diagnosed in the United States from 2001 to 2003, leukemias were the most common (26.3%). The lymphoid leukemias were the type with the highest incidence. Lymphomas, comprising 14.6% of new childhood malignant diseases, were the third most common cancers. A history of malignant disease is a common feature in the emergency department (ED) patient population. In a retrospective review of 5640 patients in a community teaching hospital with an annual ED census of 31,000, cancer history was identified in 5% of patients. Ten percent of patients with oncology-related visits died during the admission, and 48% died within 1 year of the ED visit.

PATHOPHYSIOLOGY

White blood cells (WBCs), or leukocytes, are the primary cells responsible for the inflammatory and immune response. WBCs include granulocytes (neutrophils, eosinophils, basophils) and mononuclear cells (T and B lymphocytes, monocytes). These cells are all produced from a common stem cell in the bone marrow, and they differentiate through various cytokines including colony-stimulating factors and interleukins. Normal blood leukocyte counts are 4.34 to 10.8 × 10^9/L, with neutrophils representing 45% to 74% of cells, bands representing 0% to 4%, lymphocytes representing 16% to 45%, monocytes representing 4% to 10%, eosinophils representing 0% to 7%, and basophils representing 0% to 2%. WBC disorders are the result of cell overproduction, underproduction, or dysfunction (Box 203.1). The WBC count with differential lacks specificity and sensitivity but is the most frequent laboratory test ordered by emergency physicians.

LEUKOPENIA

Leukopenia, or a WBC count less than 1.5 × 10^9/L, is most clinically relevant with significant neutropenia and its complications (primarily increased risk of infection, further outlined in Chapter 201). Although neutropenia is most common in patients with bone marrow suppression secondary to chemotherapy, Box 203.2 outlines a differential diagnosis of certain infections that characteristically manifest with neutropenia. Lymphocytopenia is a nonspecific finding that is present in many bacterial, fungal, viral, and protozoan infections.

LEUKOCYTOSIS

Leukocytosis, or an increased number of WBCs, is defined as an elevation in the total number of circulating WBCs greater than 2 standard deviations above the age-based mean circulating WBC count. This disorder is most commonly secondary to infections or systemic stressors; however, an increase in a subset of WBCs (neutrophilia, monocytosis, lymphocytosis, eosinophilia, or basophilia) may guide the differential diagnosis. Bacteria are the culprit in two thirds of infection-related cases of neutrophilia. Box 203.3 outlines infectious causes of lymphocytosis, with Bordetella pertussis being the rare bacterial exception. Eosinophilia is classically caused by multicellular parasites that invade tissue, most commonly seen in invasive parasitic disease, but it may also be seen in protozoan and fungal infections.

MORPHOLOGIC CHANGES

In addition to altered numbers, changes in cellular morphology found in a peripheral blood smear may aid in the diagnosis. A left shift (or greater percentage of immature cells, such as metamyelocytes) may be present in severe infection. Intracellular abnormalities including toxic granulations,

Cytoplasmic vacuolization, and Dohle bodies are likely secondary to infection. (Fig. 203.1).\(^6\)

**WHITE BLOOD CELL MALIGNANCY**

Although WBC disorders have a vast differential diagnosis, the remainder of this chapter focuses on hematologic malignant diseases. Leukemias, lymphomas, and plasma cell disorders are the main general categories of these malignant diseases.

Leukemias are a result of failure of differentiation of hematopoietic precursor cells that leads to unchecked proliferation of blasts, either immature myeloid or lymphoid cells, which impede the normal manufacturing of red blood cells, WBCs, and platelets in the bone marrow. Anemia, bleeding, and infection are a result of decreased normal cell production. Eventually, blasts multiply and migrate throughout other hematopoietic organs including the spleen and lymph nodes. In acute leukemias, WBC counts vary greatly (25% of patients have counts <5000/microliters, 25% have counts >50,000/microliters, and 50% have counts between 5000 and 50,000/microliters), but anemia, thrombocytopenia, and blasts are common. Bone marrow aspiration and biopsy are used to diagnose leukemias definitively.

Lymphomas are a vast group of malignant diseases defined by clonal proliferation of malignant lymphocytes. The World Health Organization lymphoma classification defined 27 types of lymphomas categorized primarily by the primary clonal cells: B cells, T cells, or natural killer cells. Lymphocytosis and varied characteristic cells are present on a peripheral blood smear. Lymph node and bone marrow biopsy also aid in the diagnosis.

Monoclonal proliferation of immunoglobulin-secreting plasma cells characterizes plasma cell disorders. These conditions include multiple myeloma, monoclonal gammopathies, Waldenström macroglobulinemia, heavy-chain diseases, cryoglobulinemia, and primary amyloidosis. These diseases are diagnosed by using serum or protein electrophoresis and bone marrow analysis.

**PRESENTING SIGNS AND SYMPTOMS**

Nonspecific presentations of liquid malignant diseases are common, but prompt recognition of these signs and symptoms is essential for rapid treatment of immunocompromised patients. Initial presentations of malignancy vary greatly from subtle historical features or physical findings to in extremis shock states typically resulting from complications and grave immunodeficiency. Patients with known malignant disease also have variable presenting complaints based on the type of malignant disease, the burden of disease, and current oncologic therapeutic regimens.

**ACUTE MYELOGENOUS AND LYMPHOID LEUKEMIAS**

**Acute Myelogenous Leukemia**

Patients with leukemia present with signs and symptoms secondary to the invasion of other organs by leukemic cells and decreased production of normal hematopoietic cells. Fever, malaise, and a viral-like syndrome are common presenting symptoms. Diffuse bony tenderness, as a result of expansion of the intramedullary space or periosteal infiltration by leukemic cells, is the initial symptom in 25% of patients.\(^9\)

Acute myelogenous leukemia (AML) typically affects all three cell lines and results in anemia, thrombocytopenia, and neutropenia. Pallor, dyspnea, and chest pain reflect anemia, whereas petechiae, ecchymosis, and excessive bleeding are a result of thrombocytopenia. One third of patients will have significant infections on diagnosis.\(^10\) Splenomegaly occurs in up to 50% of patients, and lymphadenopathy is rare.\(^9\)

AML has several skin manifestations. Raised, nontender plaques or nodules (leukemia cutis) are manifest in many forms of leukemia, but they are most commonly seen in AML (Fig. 203.2).\(^11\) Tender, pseudoexfoliated, erythematous plaques are a characteristic feature of Sweet syndrome, which may precede the diagnosis of AML by months (Fig. 203.3). Gingival hyperplasia may also be present (Fig. 203.4).
CHRONIC MYELOGENOUS LEUKEMIA
Thirty percent to 50% of patients diagnosed with chronic myelogenous leukemia are asymptomatic. Splenomegaly is present in 50% to 60%, and hepatomegaly occurs in 10% to 20% of new cases. Lymphadenopathy is rare.

NON-HODGKIN LYMPHOMA
Presentation of non-Hodgkin lymphoma is extremely variable, but patients most commonly seek medical evaluation for incidental painless, firm cervical, axillary, or inguinal adenopathy. Chest pain, cough, superior vena cava syndrome, abdominal pain, back pain, spinal cord compression, and symptoms of renal insufficiency may be present. Fevers, night sweats, and weight loss are also common symptoms.

HODGKIN LYMPHOMA
Fever, night sweats, and weight loss are the classic “B” symptoms associated with Hodgkin lymphoma. Other classic signs are systemic pruritus and painful lymphadenopathy after drinking alcohol. Painless, rubbery, supradiaphragmatic lymphadenopathy, particularly of the neck and supraclavicular nodes, is common. Less than 10% of patients will have a subdiaphragmatic presentation.

PLASMA CELL DISORDERS
Fatigue and bone pain are the most common presenting symptoms of multiple myeloma. Pain may be secondary to characteristic lytic lesions or pathologic fractures (Fig. 203.5). Focal weakness or paresthesias may be secondary to nerve root or spinal cord compression from extramedullary expansion of bony lesions.

Differential Diagnosis, Medical Decision Making, and Treatment
Once the diagnosis of a hematologic malignant disease is suspected, laboratory evaluation should be performed, including a complete blood cell count with manual differential, peripheral blood smear, chemistry studies (including uric acid,
creatinine, potassium, phosphorus, and calcium), coagulation factors, and blood type and screen. If the patient is febrile, blood cultures (aerobic, anaerobic, and fungal) should also be obtained, and empiric antibiotics should be initiated early because many of these patients have functional neutropenia, even in the setting of normal neutrophil count, and are at high risk of bacteremia or sepsis. Diagnostic imaging should be ordered based on the fociality of patients’ symptoms, but a chest radiograph is a general starting point to evaluate any of the intrathoracic complications associated with these malignant diseases. An electrocardiogram should be performed to evaluate for evidence of electrolyte abnormalities.

Patients presenting with hyperleukocytosis (an extreme elevation of the blast count or WBC count >100,000/mm³) and many different symptoms affecting multiple organ systems are at an increased risk of hyperviscosity syndrome (see Box 203.5), a medical emergency with mortality rates as high as 40%. Metabolic and electrolyte abnormalities are common. The most serious complication is tumor lysis syndrome, a result of the massive cell lysis, which releases intracellular urate, phosphate, and potassium (please refer to Chapter 201 for details on tumor lysis syndrome).

**CARDINAL PRESENTATIONS AND COMPLICATIONS OF PATIENTS WITH KNOWN WHITE BLOOD CELL CANCER**

Abdominal pain, dyspnea, fever, and malaise are all key chief complaints that require a comprehensive ED evaluation in patients with WBC disorders. Box 203.4 lists the differential diagnosis of these complaints.

**ABDOMINAL PAIN**

Gastrointestinal symptoms are the most common chief complaints of patients with cancer who present to the ED. Immunosuppressed patients represent a diagnostic challenge, because classic examination findings of an acute abdomen may be replaced by nonspecific signs or systems such as tachycardia, hypotension, and altered mental status.

In addition to disorders present in the immunocompetent host, disorders secondary either to the malignant disease or to the therapy used to combat it should be considered. Opportunistic infections, intestinal obstruction, perforation, typhlitis, and venoocclusive disease of the liver (Budd-Chiari syndrome) should be considered in the differential diagnosis of
White Blood Cell Disorders

Eventual liver failure. Symptoms include ascites, hepatomegaly, abdominal pain, jaundice, and, in severe cases, variceal bleeding and portal hypertension. Ultrasound scanning with Doppler is the initial imaging modality of choice; it has a sensitivity of more than 85%, but CT and magnetic resonance imaging are alternatives. The initial management strategy consists of sodium restriction, diuretics, anticoagulation, and periodic paracentesis. Portosystemic shunting or liver transplantation is indicated for severe forms of Budd-Chiari syndrome.

Dyspnea

Patients presenting to the ED with dyspnea should be approached with a rapid assessment of respiratory status and should be given immediate resuscitative care in the form of supplemental oxygen, assisted ventilation, or intubation with mechanical ventilation. Despite this initial universal approach to the dyspneic patient, investigation of the broad differential diagnosis is essential to formulating an emergency management plan.

Acute respiratory failure is the most common cause of admission to the intensive care unit (ICU) in patients with cancer, and it has an incidence of 10% to 50% and an overall mortality rate of 50%. Patients with leukemia and lymphoma have a higher incidence of respiratory insufficiency as the cause of ICU admission than do patients with solid tumors.

Common causes of acute respiratory failure in these patients include pulmonary infections (pneumonia), cardiogenic or noncardiogenic pulmonary edema, antineoplastic (chemotherapy or radiation) therapy-induced lung injury, venous thromboembolism, diffuse alveolar hemorrhage (DAH), airway obstruction, and underlying disease progression.

Pneumonia is the most common cause of respiratory failure in patients with hematologic malignant diseases. Streptococcus pneumoniae and Haemophilus influenzae are the most

Fig. 203.6 Typhlitis. A, Ultrasound scan showing thickened bowel wall. B, Axial computed tomography showing thickening of the wall of the ascending colon. (From Adam A, Dixon AK, editors. Grainger and Allison’s diagnostic radiology. 5th ed. Philadelphia: Churchill Livingstone; 2007.)
common organisms in patients with leukemia and myeloma (impaired B-cell immunity). Patients with Hodgkin lymphoma (impaired T-cell immunity) are more likely to be infected with Pneumocystis jiroveci, mycobacteria and fungi, and viruses (including cytomegalovirus and herpes simplex virus). Presentation may be atypical. Although fever is common, cough and sputum are not, and findings on chest radiography may be normal. Chemotherapy-induced neutropenia can give rise to infection with Staphylococcus aureus, gram-negative bacilli (Pseudomonas and Klebsiella), and opportunistic fungi (Aspergillus). Debitation, malnourishment, prolonged bed rest, and central nervous system metastasis predispose oncologic patients to increased aspiration risk.

Pulmonary edema may be cardiogenic, noncardiogenic, or a combination thereof because of several inciting events, including the use of cardiotoxic chemotherapeutic agents, infection, radiation, or transfusions. These patients are at a high risk of developing acute respiratory distress syndrome (ARDS).

Chemotherapy- and radiation-induced lung injury comprises another syndrome that may manifest with exertional dyspnea, low-grade fevers, and a nonproductive cough during or up to several months after treatment. The various diagnoses include interstitial pneumonitis, acute lung injury, ARDS, capillary leak syndrome, organizing pneumonia, hypersensitivity reaction, bronchospasm, and DAH. On examination, bilateral inspiratory crackles may be auscultated, and diffuse or patch ground-glass opacities are seen on chest radiography and CT. Each syndrome requires a multipronged approach, but cessation of the culprit chemotherapeutic agent and treatment with systemic corticosteroids are general management principles.

Venous thromboembolism (deep venous thrombosis or pulmonary embolism) is an important cause of morbidity and mortality in patients with cancer and may be a predictor of worse overall prognosis. Chemotherapeutic agents, intrinsic procoagulant tumor activity, indwelling catheters, immobilization, and surgery are risk factors for venous thromboembolism in oncologic patients. Ten percent of patients with lymphoma develop venous thromboembolism. Presenting symptoms of dyspnea, pleurisy, and palpitations and signs of tachypnea, hypoxia, and dysrhythmias should prompt a thorough evaluation for venous thromboembolism.

DAH is common in patients with leukemia or multiple myeloma, after bone marrow transplantation, and in patients with thrombocytopenia (platelets < 50,000/mm³). Total body irradiation, thoracic irradiation, and increased age are all risk factors for DAH. Patients present with progressive dyspnea, cough, and fever but rarely hemoptysis. Chest radiography may show diffuse interstitial and alveolar infiltrates, and the diagnosis is confirmed by bronchoscopy. Supportive therapy includes corticosteroids, platelet transfusions, and mechanical ventilator support.

Transfusion-related acute lung injury may develop in those patients receiving red blood cells, platelets, or fresh frozen plasma. Patients develop fever, hypotension, hypoxemia, pulmonary hypertension, and noncardiogenic pulmonary edema within 6 hours of transfusion. Treatment is supportive and often requires ventilatory support.

Airway obstruction may be secondary to locally advanced tumors in the airway or metastatic lesions to the mediastinum or tracheobronchial tree. Lymphoma may develop mediastinal masses that may cause stridor, dyspnea, hemoptysis, or cough.

Chest radiography, CT, and bronchoscopy are used in combination to establish a diagnosis and guide therapy. Definitive airway management is difficult but may be essential in these patients. Eventual treatment may consist of stents, lasers, radiation therapy, or chemotherapy.

PAIN
The most common complaint of patients with cancer who present to the ED is pain, with nausea or vomiting and weakness a close second and third most frequent chief complaints. Although pain is nonspecific, the ED physician needs to be aware of critical, life-threatening diagnoses that may manifest with pain.

Hypercalcemia may occur in up to 30% of patients with cancer, and they may present with vague symptoms of nausea, vomiting, abdominal pain, or myalgias. Hypercalcemia may lead to progressive neurologic symptoms, coma, renal failure, and arrhythmias. In multiple myeloma, hypercalcemia results from bone osteoclastic bone resorption. Lymphomas and myelomas hydroxylate vitamin D into 1,25-dihydroxyvitamin D (1.25(OH)2D), the active form of vitamin D, thus enhancing intestinal absorption of vitamin D and resulting in hypercalcemia. This diagnosis is critical in this patient population because approximately 50% of these patients will die within 30 days. The diagnosis is best made by using ionized calcium, and an electrocardiogram may show a shortened QT interval. The cornerstone of management is aggressive intravenous and oral hydration. Once volume repletion is achieved, loop diuretics are used for calcium excretion. Bisphosphonates, calcitonin, and steroids are other adjuncts, depending on the response to treatment and the primary cause of the elevated calcium concentration. Please refer to Chapter 201 for further details on hypercalcemia.

Acute blood hyperviscosity results from elevations of serum proteins (hyperviscosity syndrome) or WBCs (hyperleukocytosis) in the blood circulation. Leukocytosis and leukostasis (Fig. 203.7) have mortality rates that range from 20%

to 40%, and these conditions therefore represent an emergency diagnosis.\(^{17}\) **Boxes 203.5 and 203.6** outline the presentations and management of both conditions.

**NEXT STEPS OF CARE: ADMISSIONS**

*INPATIENT AND OUTPATIENT*

Overall patient disposition is based on clinical assessment, the ability to follow-up with a primary care physician or oncologist, and the patient’s home environment.

A patient with a new diagnosis of malignant disease may require an in-depth work-up that may be more rapidly facilitated by admission and coordination between oncology staff and primary care physicians.

For patients with a known cancer diagnosis, positive pressure isolation rooms should be considered in patients with significant neutropenia, in bone marrow transplant recipients, or in patients with other high-risk immunocompromised states (after intensive chemotherapy or solid organ transplantation). Intensive care monitoring should be reserved for patients who are critically ill, usually from complications of immunocompromise or chemotherapy.

Emergency Management of Red Blood Cell Disorders

Ugo A. Ezenkwele

KEY POINTS

- Anemia is the absolute reduction in the amount of oxygen-carrying pigment hemoglobin (Hgb) that represents a relative decrease in the capacity of blood to carry oxygen to the tissues.
- Anemia is not a diagnosis. It is an indication of an underlying disease, disorder, or deficiency.
- Transfusion of red blood cells provides immediate correction of low Hgb levels helpful in the context of either severe anemia (in which the Hgb is <8.0 g/dL) or life-threatening anemia (in which the Hgb is <6.5 g/dL).
- Most cases of anemia (chronic) do not require acute interventions and drug therapy in the emergency department (ED). Patients can be referred for follow-up to their primary care physician or gastroenterologist.
- The cardinal features of acute chest syndrome are fever, pleuritic chest pain, referred abdominal pain, cough, lung infiltrates, and hypoxia.
- Pneumococcal sepsis is a leading cause of death among infants with sickle cell anemia because a damaged spleen cannot clear pneumococci from the blood.
- Transfusions are not needed for the usual anemia or episodes of pain associated with sickle cell disease.
- Splenic sequestration is life-threatening and requires intensive care admission with transfusion and possible splenectomy.
- ED-based pain management protocols have been shown to decrease ED visits and hospitalizations and to increase use of primary care clinics by patients with sickle cell disease.
- Patients with severe pain should be given an opiate parenterally at frequent, fixed intervals until the pain has diminished, at which time the dose of the opiate can be tapered and then stopped, and oral analgesic therapy can be instituted.
- For polycythemia vera, phlebotomy is the only therapy indicated for isolated erythrocytosis when its mechanism cannot be established.

PERPECTIVE

The red blood cell (RBC) disorders include a distinct group of disease entities that are diverse in presentation yet similar in their emergency diagnosis and management. These disorders include anemia (acute, chronic), sickle cell anemia, and polycythemia vera (PV). Patients with both malignant and nonmalignant hematologic disease may present with dramatic and often life-threatening complications. Emergency management of these disorders requires a thorough understanding of the underlying pathologic processes, as well as a concise and systematic approach to diagnosis, stabilization, and treatment.

ANEMIA

EPIDEMIOLOGY

Anemia is more common than is generally realized. The World Health Organization defines anemia as a condition characterized by hemoglobin (Hgb) levels lower than 13 g/dL in men or lower than 12 g/dL in women. Data from the National Center for Health Statistics that likely underestimate the frequency of anemia indicated that approximately 3.4 million U.S. residents have anemia, and that the groups with the highest prevalence are women, African Americans, older persons, and those with the lowest incomes. Using laboratory data from the general U.S. population, the second National Health and Nutrition Survey reported anemia to be the most prevalent in infants, teenage girls, young women, and older men. In another survey, the prevalence of anemia declined significantly among U.S. women and children from 1988 to 2002, but the cause of this decline was unknown. In persons 65 years and older, anemia was present in 11.0% of men and 10.2% of women, and the prevalence rose to more than 20% in people 85 years and older. One third of the cases of anemia were the result of nutritional deficiencies, and one third of cases were secondary to chronic illness, including but not limited to chronic renal disease.
**PATHOPHYSIOLOGY**

Anemia is classified into three broad categories: (1) disorders of decreased RBC production, (2) disorders of increased RBC destruction, and (3) disorders resulting from RBC loss. Disorders in each of these categories may manifest differently and ultimately have their own management approaches (Table 204.1).

RBCs, or erythrocytes, contain fluid Hgb encased in a lipid membrane and are the predominant cellular component of blood. RBCs make up 45% of the blood volume and are responsible for carrying oxygen from the lungs to the peripheral tissues. A 70-kg person has approximately 30 trillion RBCs, resulting in approximately 300 million RBCs in each drop of blood. The normal RBC is composed of three types of Hgb: Hgb A (97%), Hgb F (1%) or fetal Hgb, and Hgb A2 (2%). Hgb A is composed of two β-globin chains and two α-globin chains bonded to four iron-containing heme groups. Hgb production requires iron, the synthesis of the protoporphyrin ring, and the production of the globin chains. Reductions in any of these processes result in anemia.

RBC precursors develop in bone marrow at rates usually determined by the body’s demand for sufficient circulating Hgb to oxygenate tissues adequately. Once produced, the mature RBC remains in circulation for approximately 120 days before it is engulfed and destroyed. Given the life span, chronic anemias that are caused by RBC underproduction generally develop and progress slowly over weeks to months. In contrast, acute anemias that are caused by bleeding or hemolysis generally occur rapidly over days to weeks. The tempo of anemia development depends on the pace of bleeding or hemolysis in relation to RBC production. The aggressiveness of intervention and management depends on the acuteness of onset and the severity of the clinical presentation.

**PRESENTING SIGNS AND SYMPTOMS**

Because anemia either can be a primary disorder or can occur secondary to other systemic processes, a careful history and physical examination provide valuable insight into the potential cause. All patients require a focused yet thorough history. For critically ill and noncommunicative patients, the history

should be obtained from caretakers, paramedics, or primary care physicians.

The extent of the symptoms, whether mild or life-threatening, depends on several contributing factors. If anemia develops acutely, compensatory adjustments may not have enough time to take hold, and consequently, the patient may have more pronounced symptoms than if the anemia developed over weeks to months. Furthermore, underlying chronic comorbidities such as myocardial ischemia and transient cerebral ischemia may be unmasked in the presence of anemia.

**ACUTE ANEMIA**

Patients with anemia resulting from acute bleeding present with hypovolemia. The combined effects of hypovolemia and anemia may cause tissue hypoxia or anoxia through diminished cardiac output, resulting in decreased oxygen-carrying capacity (anemic hypoxia). When the Hgb concentration falls to less than 7.5 g/dL as a result of losses ranging from 5% to 15% in blood volume, the resting cardiac output rises significantly, with an increase in both heart rate and stroke volume. These patients are symptomatic at rest and may be aware of this hyperdynamic state; they often complain of palpitations, lightheadedness, dizziness, or a pounding pulse. Larger losses cause progressive increases in heart rate, decreases in arterial blood pressure, and evidence of organ hypoperfusion. Hypovolemic shock is seen when vital organ systems such as the kidneys, the central nervous system, and the heart are affected.

In the emergency department (ED), a source of blood loss may be readily apparent on evaluation (e.g., trauma with hemorrhage from the extremities, gastrointestinal bleeding, menstrual blood loss); however, this may not be the case in, for example, aortic dissection or retroperitoneal hemorrhage.

Mild to moderate hypovolemia may be tolerated in the young patient. In older patients, however, these responses are modified by the rapidity of blood loss and by characteristics such as comorbid illnesses, preexisting volume status, Hgb values, and the use of medications that have cardiac or peripheral vascular effects (e.g., beta-blockers, antihypertensive agents). Therefore, the emergency physician (EP) should elicit a thorough and focused history, including medications, while assessing the airway, stabilizing breathing, and initiating resuscitation as needed.

**CHRONIC ANEMIA**

Because anemia can be a primary disorder or can occur secondary to hypoproliferation or chronic blood loss, a careful history and physical examination provide valuable insight into the potential cause. Individuals with mild anemia are often asymptomatic and are able to sustain a relatively normal level of function at Hgb levels that are significantly lower than normal. Other patients may present with myriad nonspecific symptoms (Box 204.1). Because fatigue is nonspecific, determining the concomitant presence of a systemic inflammatory disorder, infection, or malignant disease may be critical in determining the underlying causes of anemia.

Past medical history is quite informative. For instance, a history of diabetes mellitus is associated with significantly impaired renal production of erythropoietin. Certain medications are associated with bone marrow depression. Therefore, all pharmacologic agents, both prescribed and over-the-counter agents, including alternative medications, should be reviewed. Occupational history is relevant, as in the case of welders, who may have been exposed to lead or other agents potentially toxic to the bone marrow. Social history is important because a history of intravenous drug use may suggest the possibility of human immunodeficiency virus infection, which can be associated with anemia. Dietary history is relevant. For example, the finding of pica in adults (most commonly from the ingestion of nonfood items) is well known to be associated with iron deficiency anemia. A family history of anemia is important; for example, adults with congenital hereditary spherocytosis often develop symptoms later in life.

Physical findings in either acute or chronic anemia are myriad and often nonspecific, and they may relate to the underlying disease process and the duration (Table 204.2). Pathognomonic findings are not the norm. Furthermore, patients with chronic anemia usually do not have the typical physical findings associated with acute anemia.

Hgb, Hemoglobin.
The differential diagnosis of anemia is myriad, as documented in Table 204.3. Once anemia is suspected, the initial diagnosis involves the complete blood count (CBC). The variables to focus on when examining the CBC are hematocrit (as a general indicator of anemia or polycythemia), mean corpuscular volume (MCV) a key parameter for the classification of anemias), RBC distribution width (a relatively useful parameter in the differential diagnosis of anemia), RBC count (an increased RBC count associated with anemia is characteristic in the thalassemia trait), platelet count (to detect either thrombocytopenia or thrombocytosis), and white blood cell (WBC) count with differential (usually gives important clues to the diagnosis of acute leukemia and chronic lymphoid or myeloid disorders, as well as clues to the presence of leukopenia and neutropenia).8

Blood type and cross should be sent to the blood bank so that type-specific or type-matched and crossmatched blood can be readied. Other tests to obtain are unconjugated bilirubin and lactate dehydrogenase. These values are increased when RBCs are destroyed. In patients with severe intravascular hemolysis, the binding capacity of haptoglobin is exceeded rapidly, and free Hgb is filtered by the glomeruli, thus leading to decreased haptoglobin and increased hemoglobinuria or urobilinogen levels.

Imaging studies are disease specific and depend on the patient’s symptoms. Chest radiographs are indicated in all patients with significant anemia. Cardiomyopathy may be present in patients with chronic anemia. An electrocardiogram is required for older patients, those with chest pain, patients with profound anemia, or those who have an underlying disease or increased risk factors for cardiac ischemia.

Patients with blood loss may benefit from an ultrasound examination, which is a quick, noninvasive, and relatively simple bedside test useful for diagnosing intraperitoneal bleeding. The focused abdominal sonography for trauma (FAST) examination detects blood in the hepatorenal fossa, paracolic gutters, splenorenal area, and pelvis. Ultrasound is
also useful for detecting pregnancy-related bleeding, especially that emanating from a ruptured ectopic pregnancy. Stable patients with intraabdominal blood loss benefit from computed tomography (CT) scanning. CT scanning has sensitivities similar to those of ultrasound, yet it identifies causes, including retroperitoneal, pelvic, and subcapsular sites, more clearly.

A nasogastric tube may be indicated in the acute setting to diagnose and manage an ongoing upper gastrointestinal hemorrhage. Bile must be aspirated to rule out bleeding proximal to the ligament of Treitz. Once upper gastrointestinal bleeding is established, esophagogastroduodenoscopy is the study of choice for determining the source of bleeding and for treatment. Emergency esophagogastroduodenoscopy can be performed in the ED, and its use is indicated in the hemodynamically unstable patient. Consultation with a gastroenterologist is required. Sigmoidoscopy or colonoscopy may be useful in diagnosing and treating lower gastrointestinal bleeding, but it is rarely helpful in the acute setting.

TREATMENT

After anemia is identified by a CBC determination in the ED, management is aided by an approach that categorizes anemia as a symptom caused by the decrease in Hgb, rather than as an isolated diagnosis (see the “Priority Actions” box). Like fever, anemia is a symptom of disease that requires investigation to determine the underlying origin.

PRIORITY ACTIONS

1. Determine the patient’s hemodynamic status. The need for transfusion is often limited to those in hypovolemic shock.
2. If the patient is unstable, initiate resuscitation with crystalloids.
3. Once the patient is stabilized, blood transfusions are widely used as a rapid and effective therapeutic intervention in the context of either severe anemia (Hgb < 8.0 g/dL) or life-threatening anemia (Hgb < 6.5 g/dL).9
4. Look for the underlying cause and attempt to correct it.

Hgb, Hemoglobin.

Patients with long-standing or chronic anemias are able to compensate and do not require transfusion, especially if the Hgb is greater than 9.0 g/dL. Patients who are expected to respond to the administration of a specific agent such as folic acid, iron, or vitamin B₁₂ can usually be spared transfusions. If the anemia has precipitated an episode of congestive heart failure or myocardial ischemia, prompt administration of packed RBCs is indicated. For some patients in the ED, treatment can be begun without waiting for a definitive outpatient evaluation. For example, prenatal vitamins and iron replacement can be begun in the pregnant patient with anemia. In symptomatic pregnant patients, parenteral iron is preferred.10 Megaloblastic anemia resulting from folic acid or vitamin B₁₂ deficiency can be treated with parenteral cobalamin (1000 g/day) or oral folic acid (1 mg/day). Erythropoietin therapy remains an option for patients undergoing elective surgical procedures or receiving chemotherapy and in patients with chronic heart failure or acquired immunodeficiency syndrome. In the acute setting, however, specifically in symptomatic heart failure, the role of erythropoietin therapy remains to be defined.11,12

DISPOSITION

Fortunately, most patients have chronic anemia without blood loss and can be managed conservatively. In many cases, acute interventions and drug therapy are not indicated in the ED, and patients can be referred for follow-up to their primary care physicians.

Emergency consultation and hospital admission are required for patients presenting with hypovolemia or active bleeding who demonstrate a considerable drop in Hgb and hematocrit values when compared with previous values. A Hgb value of less than 8.0 g/dL in a symptomatic patient is enough to warrant admission for replacement of blood products. Patients who have underlying disease such as cardiac ischemia or congestive heart failure and who are now symptomatic and complaining of chest pain, tachypnea, or shortness of breath because of their anemia also require admission. Patients with new-onset or worsening pancytopenia require urgent consultation. Finally, admission is indicated for those patients who may not comply with follow-up or those in whom the clinician anticipates the need for an extensive work-up. Admission is to a medical ward bed, intermediate unit, or intensive care bed, depending on the patient’s presenting symptoms.

SICKLE CELL ANEMIA

Epidemiology

Sickle cell disease (SCD), characterized by lifelong hemolytic anemia and many different painful and debilitating vasocclusive events, occurs in 70,000 to 80,000 U.S. residents of African, Mediterranean, or Middle Eastern descent. In the United States, the life expectancy for patients with SCD is shortened by approximately 30 years, whereas in Africa, where comprehensive medical care is less readily available, death in early childhood is usual.13 Eight percent of African Americans are heterozygous carriers of the sickle cell trait; approximately 40% of their Hgb is Hgb S. They do not have anemia and need neither treatment nor occupational restrictions.

Pathophysiology

SCD is an inherited condition caused by a point mutation in the β-globin gene (Hgb B) that causes the substitution of valine for glutamic acid at position 6 of the β-globin chain (Glu6Val). This mutation results in the abnormal Hgb S¹⁴ (Fig. 204.1). When deoxygenated, Hgb S polymerizes, thus damaging the sickle RBC. These sickle cells are short-lived
and interact with endothelial cells, WBCs, platelets, and other plasma components to initiate the vasoocclusive manifestations associated with SCD. Among hemolytic anemias, the vasoocclusive features of SCD are unique. By occluding small blood vessels and sometimes large vessels, sickle cells cause vascular injury (Fig. 204.2).

**PRESENTING SIGNS AND SYMPTOMS**

Vasoocclusion, which is responsible for most of the severe complications of SCD, can occur wherever blood flows. The clinical features of SCD are outlined in Table 204.4.

**PAINFUL EPISODES**

Acute painful crisis in SCD is a frequent complication and considerably diminishes the quality of life of patients with this disease. Approximately 60% of patients have an episode of severe pain. A few patients have severe pain almost constantly. Episodes of pain are sometimes triggered by infection, extreme temperatures, or physical or emotional stress, but more often they are unprovoked and begin with little warning.

**ACUTE CHEST SYNDROME**

The *acute chest syndrome* is the leading cause of death and hospitalization among patients with SCD. Affecting approximately 40% of all patients with sickle cell anemia, it is the second most common reason for hospitalization and the leading cause of intensive care unit admission and premature death in patients with SCD. Its cardinal features are fever, pleuritic chest pain, referred abdominal pain, cough, lung infiltrates, and hypoxia. It is most common but least severe in children, can occur postoperatively, and when recurrent, can lead to pulmonary hypertension, restrictive lung disease, and eventually right-sided heart failure and death.

Asthma has been associated with multiple complications of SCD, including acute chest syndrome. Asthma is an independent risk factor for mortality in children with SCD, and it confers a twofold higher risk of death.

**CEREBROVASCULAR CRISIS**

Cerebrovascular disease is the second leading cause of mortality and a common cause of morbidity in sickle cell anemia: approximately 10% of patients have a clinical stroke by age 20 years, and another 22% have evidence of silent infarction on magnetic resonance imaging. Manifestations of neurologic complications may include overt clinical stroke or subtler neuropsychological abnormalities often associated with subclinical stroke. Risk factors for ischemic stroke presentation in SCD include prior transient ischemic attacks, a decrease in steady-state Hgb, a history of acute chest syndrome, and an increase in systolic blood pressure. Risk factors for hemorrhagic stroke include a decrease in steady-state Hgb and an increase in steady-state WBC.

**RIGHT UPPER QUADRANT SYNDROME**

*Right upper quadrant syndrome* is manifested by any or all of the following features: hyperbilirubinemia, abdominal pain, fever, right upper quadrant abdominal tenderness, hepatomegaly, abnormalities on liver function testing, and hepatic failure. Possible causes include cholelithiasis, viral hepatitis, biliary cholestasis, and hepatic ischemia. Cholelithiasis occurs in children as young as 3 to 4 years of age and is eventually found in approximately 70% of patients; this condition often necessitates cholecystectomy once right upper quadrant pain is identified.

The three acute hepatic syndromes seen in SCD are acute hepatic cell crisis, acute hepatic sequestration crisis, and sickle cell intrahepatic cholestasis. Intrahepatic cholestasis is benign and may be associated with severe hyperbilirubinemia that resolves in 7 to 10 days, especially in children. A syndrome more common in adults is associated with fever, leukocytosis, abdominal pain, and deteriorating liver function, as indicated by measurement of liver enzymes. This hepatic crisis usually progresses to hepatic failure, coagulopathy, encephalopathy, and death.

**PRIAPISM**

Priapism is a sustained, painful, and unwanted erection of the penis that pathophysiologically is the result of an accumulation of sickled RBCs in the corpora cavernosa that cause ischemia or low flow. Approximately 30% of male patients with SCD who are less than 20 years old report at least one episode of priapism, whereas frequencies of 30% to 45% are estimated for adult men. This condition is most common in patients with the greatest amount of hemolysis. Postpubertal male patients tend to have more prolonged episodes of priapism and have a less favorable prognosis for future potency. One sequela is impotence; therefore, for the EP, the utmost priority in these patients is detumescence, especially within the first 12 hours.

**SPLENIC SEQUESTRATION**

Splenic sequestration, caused by sickled cells trapped in the splenic circulation, results in precipitous decreases in Hgb concentration and rapid enlargement of the spleen. This condition may be life-threatening. It is common in infants and young children and is less common in older children and adults because the spleen is significantly fibrotic in these patients by the age of 5 years. *Acute splenic sequestration crisis* generally is defined as an acute drop in Hgb levels (>2 g/dL) associated with splenomegaly, reticulocytosis, and signs of intravascular volume depletion. Drops in Hgb levels greater than 4 g/dL are associated with 35% mortality. Splenic sequestration carries a 15% mortality rate and is the second leading cause of death among children. It may manifest as hypotension (caused by shock from worsening anemia) associated with an enlarged, tender spleen. Fatigue, listlessness, and pallor have also been described. An association between this crisis and acute viral infections exist, especially parvovirus B19 infection.

**TRANSIENT APLASTIC CRISIS**

Aplastic crisis occurs in children with sickle cell anemia in response to transient suppression of erythropoiesis, most often because of infection with parvovirus B19, the same etiologic agent that causes erythema infectiosum (“fifth disease”). This crisis is usually a unique event in the life of a patient and suggests the induction of long-lasting, protective immunity. Although self-limited, aplastic crisis can cause severe, occasionally fatal, anemia that precipitates congestive heart failure, cerebrovascular accidents, and acute splenic sequestration. WBC and platelet counts may fall somewhat during transient aplastic crisis, especially in patients with functioning spleens. Aplastic crisis may be also be precipitated by other infections, including infections with *Streptococcus pneumoniae*, other streptococci, *Salmonella*, and Epstein-Barr virus. Children present with signs of severe anemia, such as tachycardia and pallor.

**STREPTOCOCCUS PNEUMONIAE SEPSIS**

The incidence of invasive *S. pneumoniae* infection is 20- to 100-fold higher in children with SCD than in the general population. Penicillin prophylaxis for children with sickle cell anemia reduces the incidence of invasive pneumococcal infection by 84%, independent of pneumococcal immunization status.

**DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTING**

Patients with SCD frequently require immediate medical attention because of the severity of their disease and its potential complications. Understanding the various presenting symptoms and staying alert for severe manifestations of the disease are important for EPs (see the “Priority Actions” box). Diagnostic testing is often focused, depending on the presenting symptoms. In most patients, however, a basic set of laboratory tests should be obtained. Baseline laboratory values are helpful, as well as knowledge of the patient’s medication history, the severity and frequency of previous crisis, and any surgical complications.

Emergency management depends on clinical presentation and can be symptom specific. Patients with known SCD should have a CBC and a reticulocyte count. These tests are necessary to help screen for severe anemia, aplastic crisis, sequestration crisis, and infection. A major drop in Hgb (e.g., >2 g/dL) from baseline values indicates a hematologic crisis.
Chapter 204: Emergency Management of Red Blood Cell Disorders

**Priority Actions**

<table>
<thead>
<tr>
<th>Bony Pain?</th>
</tr>
</thead>
<tbody>
<tr>
<td>Does the patient have evidence of trauma or infection?</td>
</tr>
<tr>
<td>If not, consider osteomyelitis. Although Salmonella is commonly described, Staphylococcus aureus is the predominant organism. Admit for intravenous antibiotics.</td>
</tr>
</tbody>
</table>

**Diffuse or Isolated Pain?**

- Does the patient have any identifiable triggers (i.e., infection, dehydration, hypoxia, pregnancy, cold exposure, acidosis, recent flight in unpressurized aircraft)?
- If yes, assess and treat underlying cause. If not, consider whether this is a usual vasoocclusive crisis; inquire about onset, duration, location, and a history of previous episodes. Treat with analgesics, preferably opiates.

**Abdominal Pain, Nausea, and Vomiting?**

- Does the patient have pancreatitis, appendicitis, peptic ulcer disease, diverticulitis, colitis, or renal colic?
- If not, consider symptomatic cholelithiasis, acute hepatic crisis, or splenic sequestration. Obtain right upper quadrant ultrasound imaging, check transaminases, and consider surgical consultation. Consider transfusion for severe anemia.

**Focal Neurologic Deficits (Hemiplegia, Aphasia, Paresthesias) or Seizures?**

- Does the patient have hypertension, coronary artery disease, or atrial fibrillation with a possible thromboembolic phenomenon?
- If not, consider vasoocclusion in the cerebral circulation. Obtain an emergency computed tomography scan and neurologic consultation, and consider red blood cell apheresis.

**Productive Cough with Fever?**

- Does the patient have high fever, leukocytosis, positive Gram stain, or evidence of pneumonia on radiographs?
- If not, consider acute chest syndrome, especially with low-grade temperature and vasoocclusive symptoms elsewhere. Obtain a chest radiograph and blood cultures. Admit for observation and possible exchange transfusion.

**Child with Fever Greater Than 101.3°F?**

- Does the patient have pneumonia, pyelonephritis, cholangitis, cholecystitis, osteomyelitis, or meningitis?
- If not, consider sepsis. Obtain a complete blood count, urinalysis, urine and blood cultures, chest radiograph, and lumbar puncture. Pneumococcal sepsis is a leading cause of childhood mortality, with a 14% mortality rate.

**Pallor, Fatigue, Listlessness, or Recent Viral Illness?**

- Consider aplastic anemia. Obtain a reticulocyte count. Treatment is supportive and depends on the degree of anemia and hemodynamic instability.

**Abdominal Pain with Enlarged Spleen?**

- Splenic sequestration is life-threatening and requires intensive care admission with transfusion and possible splenectomy.

**Painful, Erect Penis?**

- Does the patient have paraphimosis, phimosis, or recent trauma?
- If not, consider priapism. Obtain urology consultation, and initiate oral terbutaline or pseudoephedrine. Intracavernosal injection with α-adrenergic agonist is warranted. Also, treat with hydration, analgesia, ice packs, and exchange transfusions.

If the reticulocyte count is normal, splenic sequestration is the probable cause. If the reticulocyte count is low, bone marrow failure is the probable cause. An infection is indicated by major elevations in the WBC count (e.g., >15,000/mm³) accompanied by a left shift and significant bandemia. In interpreting these values, the EP should know that most patients with SCD have chronic anemia (hematocrit of 20% to 30%), mild leukocytosis, elevated reticulocyte counts, and thrombocytosis.

Serum electrolytes, blood urea nitrogen, and creatinine levels are essential to determine when hydration status and metabolic function are concerns. However, these values are not always needed, especially in mild disease. Any toxic-appearing patient in respiratory distress requires arterial blood gas analysis, to establish a baseline and to diagnose acidaemia abnormalities. Continuous pulse oximetry monitoring is warranted and reliable.

A type and crossmatch are sent to the blood bank, in case transfusion is required. Measurement of prothrombin and partial thromboplastin times are indicated to evaluate for hypercoagulable states, especially in patients demonstrating evidence of thrombotic disease, including stroke, and myocardial ischemia.

Patients with abdominal pain require liver function tests and serum lipase evaluations. An elevated baseline indirect bilirubin level may be normal because of chronic hemolysis. Extreme elevation may indicate cholelithiasis and cholecystitis. Patients with chest pain require an electrocardiogram to screen for myocardial ischemia.

The urine must be examined for evidence of infection if the patient has fever or signs of urinary tract infection. Hematuria and isosthenuria are often present in patients with SCD. If signs of urinary tract infection are present, a urine Gram stain and culture should be obtained. Patients with fever without clear evidence of pneumonia, cholecystitis, pyelonephritis, or apparent source require blood cultures, preferably two sets.

Imaging studies are also symptomatic specific. A chest radiograph is indicated in all patients with respiratory symptoms, including productive cough and tachypnea. Radiographic findings in acute chest syndrome may be normal in the early stages of presentation. Bone radiographs are necessary in patients with localized bony pain if osteomyelitis is suspected. Although not readily available in the ED, bone scans may be used to confirm the diagnosis. Ultrasonography is necessary in patients with abdominal pain to rule out cholecystitis, cholelithiasis, hepatomegaly, and splenomegaly. Patients with new neurologic signs and symptoms require CT scanning or magnetic resonance imaging of the head.
SECTION XX  ■  HEMATOLOGY AND ONCOLOGY MANAGEMENT

TREATMENT

Treatment of SCD is evolving. The description of barriers to effective pain management is interesting and has been well documented. Patients tend to undertreat their patients because they fear patients’ dependence on pain medication, which in reality is present in only 1% to 3% of patients. Patients with SCD who are in pain are also misunderstood because they display a different attitude to their severe pain than do trauma or oncology patients. Although patients with SCD complain of severe pain, they may engage in activities that are inconsistent with the traditional image of the patient in severe pain, such as watching television or talking on the telephone. These patients are therefore often perceived as exaggerating their pain to receive additional narcotics, whereas these activities may actually be learned distractions or coping mechanisms. Another example is the sleeping patient who, when awakened, reports unrelenting pain. This situation may stem from an imbalance between the sedative and analgesic effects of opiates or a need for sleep despite the pain. The result is a lack of trust between patients and health care providers. In centers specializing in sickle cell crises, the attitudes toward pain tend to be better understood, and treatment outcomes are superior, compared with EDs.

Oral analgesics suffice for treating mild to moderate pain. Patients with mild to moderate pain seem to find no difference between intravenous and oral morphine. Most opiates have comparable efficacy and safety profiles, but morphine (0.1 mg/kg) is considered the drug of choice for treatment of acute sickle cell pain. Hydromorphone (1.5 mg) may be used if morphine is unable to achieve effective analgesia. In children, studies emphasize oral dosing of potent opioids (weight-based dosing) and nonsteroidal antiinflammatory drugs, home treatment, and reduced reliance on EDs or inpatient admission. A pain protocol, if available, should be used (Box 204.2). ED-based pain management protocols have been shown to decrease ED visits and hospitalizations and to increase use of primary care clinics by patients with SCD.

Patients in severe pain should be given an opiate parenterally and preferably initiated within 15 to 20 minutes. The opiate should be dosed at frequent (15 to 30 minutes), fixed intervals, not as needed, until the pain has diminished, at which time the dose of the opiate can be tapered and then stopped, and oral analgesic therapy can be instituted.

When available and appropriate for the treatment of acute pain, patients prefer patient-controlled analgesia (PCA) to scheduled dose or continuous infusion of morphine. When used to treat acute pain episodes, PCA results in similar pain relief with lower morphine consumption when compared with continuous infusion of morphine. Furthermore, when introduced in the ED for the treatment of acute pain, PCA use was associated with a shorter elapsed time between onset of pain and treatment. These data, along with clinical experience, suggest that PCA has emerged as a standard for the treatment of acute pain, and, if possible, it should be started in the ED.

The use of meperidine is discouraged because of the risk of seizures. Many opioid side effects can be ameliorated by drug therapy directed at the side effect (e.g., antiemetics to treat nausea and vomiting, antihistamines to treat itching, laxatives to treat constipation). Antiinflammatory drugs and intravenous methylprednisolone may provide an opiate-sparing effect, but concern exists about their negative effects on bone healing. In addition, painful crises seem to recur frequently after treatment with methylprednisolone.

Urgent replacement of blood is often required for sudden severe anemia occurring in children when blood is sequestered in an enlarged spleen or when parvovirus B19 infection causes transient aplastic crisis. For aplastic crisis, clinical management is supportive and depends on the degree of anemia and cardiovascular compromise. Simple transfusions are administered to raise the Hgb to approximately 10 g/dL and the hematocrit to approximately 30% if the reticulocyte count is less than 1% to 2% with no signs of spontaneous recovery. Increasing the Hgb level to more than 11 g/dL is not recommended because of increased viscosity and risk of vaso-occlusion. For shock caused by splenic sequestration, emergency management is aimed at restoring circulating blood volume and hemodynamic stability through the infusion of crystalloids and volume expanders and by repeated simple or exchange blood transfusions. Ultimately, splenectomy may be performed because sequestration has been shown to recur in 50% of patients and represents a life-threatening event. Admission is required for patients with aplastic crisis and

**BOX 204.2 Emergency Department–Based Pain Protocol**

- Determine patients’ previous known requirement for analgesia.
- Determine drug allergies and document the type of reaction.
- All patients should receive ibuprofen, 600 mg PO × one dose, unless a contraindication exists.
- Morphine is the drug of choice; hydromorphone is preferred in morphine-allergic patients.
- Evaluate pain: patients with severe pain requiring IV opioids or moderate pain able to take PO opioids.

**Severe Pain**

- Administer morphine, 5 to 10 mg IV initial dose, then 4 to 6 mg every 5 to 10 minutes, or hydromorphone, 1.5 mg IV initial dose, then 0.5 to 1 mg IV every 5 to 10 minutes.
- Titrate to comfort.
- Start IV PCA.
- If PCA demands fewer than 3, wean off IV PCA, and discharge with a standing dose of ibuprofen, Percocet (acetaminophen and oxycodone), morphine SR, or hydromorphone.
- If PCA demands more than 3, admit the patient.

**Moderate Pain**

- Administer morphine liquid, 10 mg PO × one dose or hydromorphone tablet, 2 mg PO × one dose.
- Reassess at 10 minutes.
- If no relief occurs, treat with IV opioids.
- If relief occurs, discharge the patient with a standing dose of ibuprofen, Percocet (acetaminophen and oxycodone), morphine SR, or hydromorphone.

*PO, orally; SR, sustained release.*
splanic sequestration. Transfusions are not needed for the usual anemia or episodes of pain associated with SCD.28

Treatment of acute chest syndrome is supportive and may include supplemental oxygen to maintain arterial oxygen saturation at more than 92%. Analgesia and incentive spirometry can minimize chest wall splinting and thus prevent atelectasis and hypoxemia.29 Pulse oximetry in patients with SCD has shown to correlate with arterial oxygen content. Antibiotics should be given to treat infections with *S. pneumoniae*, *Haemophilus influenzae*, and atypical organisms such as *Mycoplasma*, *Legionella*, and *Chlamydia*. Frequently, a macrolide with a third-generation cephalosporin is chosen. In acute chest syndrome, simple transfusion has been demonstrated to be more effective than exchange transfusion.29 Given the increased proclivity of patients with SCD to develop alloantibodies, the potential negative effects of a higher Hgb level after exchange, and the time and the expense of both the pheresis procedure and the vascular access insertion, EPs should initiate simple transfusions first in the event that the Hgb is less than 30%.

Acute hepatic cell crisis manifests with tender hepatomegaly, worsening jaundice, and fever. This syndrome usually resolves within 3 to 14 days with supportive care alone, but it can progress to liver failure, which carries a dismal prognosis. Exchange transfusion should be considered for patients with signs of progressive liver dysfunction.

Sepsis is a leading cause of death, especially in younger children. Management incorporates the following: (1) treatment of the infection with source control and antimicrobial agents; (2) rapid and targeted resuscitation from shock with administration of fluid (and, if appropriate, blood products), vasopressors, or inotropic agents; (3) adjuvant therapy with recombinant human activated protein C or corticosteroids in carefully selected patients; and (4) supportive measures such as lung-protective ventilation for acute respiratory distress syndrome. Appropriate cultures of blood and material from other sites should be quickly obtained, and broad-spectrum intravenous antibiotics should be started within the first hour after severe sepsis or septic shock is recognized. All patients who have high fevers and who are not receiving prophylactic penicillin should receive intravenous ceftriaxone as a precaution against meningitis from *S. pneumoniae* and *Neisseria meningitidis*. Patients with osteomyelitis should be treated for infection with *Salmonella* and *Staphylococcus aureus*. Patients with presumed urinary tract infections, especially pyelonephritis, should receive treatment for *Escherichia coli* infection.

Hydroxyurea increases the production of Hgb F in patients with sickle cell anemia and thus ameliorates the disease clinically. The only successful therapeutic strategy so far for SCD is based on the use of hydroxyurea to increase the RBC content of Hgb F. Substantial reductions in pain rate, acute chest crises, and transfusion requirements have been achieved with hydroxyurea therapy. Long-term follow-up (9 years) of hydroxyurea-treated patients showed a 40% reduction in mortality with this therapy. The use of this agent in the ED is limited. Other interventions as described previously should be initiated earlier.

Novel therapies may include dipyridamole (Persantine), which has been shown to be a powerful inhibitor of the deoxygenation-induced fluxes of sickled cell polymerization, especially in dehydrated cells in vitro. However, more clinical trials are needed to demonstrate this benefit in vivo. Low-dose, longer-acting glucocorticoids, especially dexamethasone, have shown a benefit in the management of acute chest syndrome. However, more research is also needed. More recent studies and ongoing clinical trials have hypothesized that inhaled nitric oxide may be beneficial in managing various clinical conditions, including sickle cell anemia.29 However, because the delivery of inhaled nitric oxide may have more limited applicability in the clinical setting as a result of inherent administration problems, the oral administration of L-arginine (precursor of nitric oxide) shows promise as a potential treatment for vasoocclusive crises and acute chest syndrome.31

**DISPOSITION**

Patients with SCD who have uncomplicated painful crises and who receive hydration and adequate pain relief in the ED can be discharged. Adequate pain relief can be achieved on a variable basis for different patients, and no set rule exists about when this occurs. Some practitioners advocate for either temporal observation in the ED (6 hours) or a set amount of parenteral analgesics, most commonly opioids (two or three trials). Failure to achieve adequate pain relief requires inpatient admission (see the “Red Flags” box).

**RED FLAGS**

**Indications for Hospital Admission**

- Inability to control pain
- Inability to maintain adequate hydration
- Acute chest syndrome
- Bacterial infection with unexplained fever, leukocytosis
- Cerebrovascular crisis (new neurologic sign or symptom)
- Priapism
- Splenic sequestration
- Aplastic or hemolytic crisis
- Acute abdomen, especially right upper quadrant syndrome
- Noncompliance with follow-up schedules
- Uncertain diagnosis

In the absence of contraindications (temperature > 38°C, respiratory signs or symptoms, low arterial oxygen saturation, tachycardia, or hypotension) and if adequate pain relief is attained, patients can be discharged home on a regimen of oral analgesics for 1 week, with continuity of care arranged. Patients who have minor infections can be discharged with oral antibiotics, more commonly amoxicillin-clavulanate, azithromycin, or levofloxacin. Primary care physicians should be contacted, and specialist care (hematology) referral should be arranged. Finally, counseling is indicated to prevent future crises, given the chronic nature of SCD. Preventive measures include advising the patient to adhere to an immunization schedule (especially pneumococcal, influenza, and hepatitis vaccines), to maintain biannual health care visits, and to take advantage of oral penicillin prophylaxis for patients with frequent infections.
**POLYCYTHEMIA VERA**

**EPIDEMIOLOGY**

PV is traditionally classified as a myeloproliferative disorder, which is a broad category of clonal stem cell diseases that include myelofibrosis with myeloid metaplasia and chronic myeloid leukemia. The true incidence and prevalence of PV are unknown. PV is relatively rare, occurring in 0.6 to 1.6 persons per million population. The disease has been recognized since the early twentieth century, and the initial description as presented by Osler has not changed. Fortunately, PV has the survival characteristics of a benign disease, and much still needs to be learned. For the EP, understanding the complications of the disease ultimately aids in its management.

**PATHOPHYSIOLOGY**

The Greek term polycythemia is synonymous with the word erythrocytosis, and it literally translates as “many cells in the blood.” Absolute polycythemia is a condition with increased RBC mass. Numerous primary and secondary polycythemic disorders lead to absolute polycythemia.

Primary and secondary polycythemias can be either acquired or congenital. Congenital polycythemias may result from inherited appropriate responses to tissue hypoxia, acquired conditions characterized by autonomous erythropoietin production (secondary polycythemias), defects in hypoxia sensing (either primary or secondary polycythemia), or inherited intrinsic defects in RBC precursors that render erythropoietin hypersensitive to erythropoietin (primary familial and congenital polycythemia).

PV, the most common primary polycythemia, is caused by the somatic change of a single hematopoietic stem cell, thus leading to clonal hematopoiesis. The molecular defects responsible for PV are unknown.

**PRESENTING SIGNS AND SYMPTOMS**

Symptoms of PV are related to hyperviscosity, sludging of blood flow, and thromboses, which lead to poor oxygen delivery and symptoms that include headache, dizziness (vertigo), tinnitus, visual disturbances, angina pectoris, and intermittent claudication. Hypertension is common in patients with PV.

Bleeding manifestations in PV involve primarily the skin and mucous membranes, findings suggesting defective primary hemostasis, and include ecchymosis, epistaxis, menorrhagia, and gingival hemorrhage. Gastrointestinal hemorrhage occurs less frequently but can be severe, necessitating hospitalization and blood transfusion, and it is often associated with the use of aspirin. This type of bleeding pattern is consistent with platelet defects (quantitative or qualitative) or von Willebrand disease.

Thrombosis, hemorrhage, and systolic hypertension result from the hyperviscosity associated with RBC mass expansion. Historically, thrombosis, both venous and arterial, occurred in up to 40% of patients during the course of the illness.

Dyspepsia and gastric or peptic ulceration appear to be more common in patients with PV than in the general population. The most serious complication other than thrombosis is pruritus.

Physical findings in PV are the result of manifestations of the myeloproliferative process and include splenomegaly (present in 75% of patients) and hepatomegaly (present in ~30% of patients). Plethora or a ruddy color results from the marked increase in total RBC mass. This manifests in the face, palms, nail beds, mucosa, and conjunctiva.

**DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTING**

PV is a clinical diagnosis. Diagnostic tests are nonspecific, sometimes uninformative, and none of them establish clonality. The diagnosis is currently facilitated through the laboratory measurement of RBC mass, plasma volume, and arterial oxygen saturation and determination of oxygen pressure at 50% Hgb saturation. In the ED, elevated RBC counts and hematocrit values (including Hgb levels) are used to make this diagnosis. Generally, Hgb concentrations of at least 20 g/dL or hematocrit values of at least 60% in male patients and 56% in female patients can be presumed to indicate a myeloproliferative disorder. Direct measurement of the RBC mass should show an increase, with a normal or slightly decreased plasma volume. However, this nuclear medicine test uses radiochromium-labeled RBCs to measure actual RBC and plasma volume. None of them is routine or specific to PV. Therefore, PV should be considered if a clinical picture suggests the diagnosis. The most serious complication other than thrombosis is pruritus.

Physical findings in PV are the result of manifestations of the myeloproliferative process and include splenomegaly (present in 75% of patients) and hepatomegaly (present in ~30% of patients). In the absence of other manifestations of disease, phlebotomy is the only therapy indicated for isolated erythrocytosis when the mechanism cannot be established. Phlebotomy can be initiated in the ED; however, a hematology consultation is required. Other agents such as aspirin, various antihistamines, synthetic androgens, and phototherapy have been described, and initiation of these therapeutic adjuncts can be carried out on an inpatient basis.

Finally, splenectomy is an option for patients with painful splenomegaly or repeated episodes of thrombosis that cause splenic infarction. At this juncture, inpatient evaluation is warranted, and surgical consultation should be obtained.

whether the patient has an associated life-threatening condition (Box 205.1).

### IDIOPATHIC OR IMMUNE THROMBOCYTOPENIC PURPURA

#### EPIDEMIOLOGY

Immune thrombocytopenic purpura (ITP) is an autoimmune disorder characterized by isolated thrombocytopenia. The estimated incidence is 100 cases per 1,000,000 patients, and half of the cases are seen in children. In children, the gender distribution is equal, whereas in adults, women are three times more likely to be affected than are men. ITP is defined as chronic if it lasts for longer than 6 months. Eighty percent of children with ITP have the acute form, whereas 80% of adults with ITP develop the chronic illness.

#### PATHOPHYSIOLOGY

Thrombocytopenia in ITP is primarily the result of accelerated platelet destruction. Autoantibodies bind to platelet antigens and thus lead to accelerated clearance by macrophages found primarily in the spleen and the liver. This increased clearance is magnified by decreased production caused by intramedullary destruction of platelets and megakaryocyte inhibition. Thrombocytopenia, in turn, leads to bleeding through loss of the integrity of the vascular wall and deficits in thrombus formation.

#### PRESENTING SIGNS AND SYMPTOMS

ITP is classically described as occurring after a prodromal infection. This presentation accounts for 60% of cases in patients 1 to 10 years of age. Outside this age range, thrombocytopenia occurs without any preceding symptoms and is often found incidentally.

Patient’s symptoms of bleeding depend on the severity of the thrombocytopenia. Patients with platelet counts higher than 50,000/mm³ are asymptomatic. Patients with platelet counts lower than 50,000/mm³ may report easy bruising with
BOX 205.1 Differential Diagnosis of the Patient with Thrombocytopenia

**Possible Disorders**
- ITP
- TTP-HUS
- HELLP syndrome or preeclampsia
- Acute infections or sepsis
- Drug-induced thrombocytopenia
- DIC
- Malignant hypertension
- Hematopoietic malignant diseases
- Myelodysplastic syndromes

**Physical Examination Findings**
- Petechiae
- Subconjunctival hemorrhage
- Guaiac-positive stools
- Bruising

**Laboratory Findings**
- ITP
  - Isolated thrombocytopenia
  - No other cytopenias
  - Normal chemistries and normal coagulation studies
- TTP-HUS
  - Thrombocytopenia
  - Anemia
  - Schistocytes
  - Negative Coombs test
  - Elevated lactate dehydrogenase
  - Normal coagulation studies
  - Signs of organ dysfunction (i.e., creatinine, troponin, LFT elevations)
  - Increased reticulocyte and decreased haptoglobin
- DIC
  - Thrombocytopenia
  - Anemia
  - Elevation of coagulation studies
  - Elevated d-dimer
  - Elevated fibrin split products
- Heparin-induced thrombocytopenia
  - Thrombocytopenia (relative or absolute)
  - Normal coagulation studies
  - Elevated platelet factor 4 antibodies

DIC, Disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, low platelets; ITP, immune thrombocytopenic purpura; LFT, liver function test; TTP-HUS, thrombotic thrombocytopenic purpura–hemolytic uremic syndrome.

Minor trauma, whereas patients with platelet counts between 10,000 and 30,000/mm³ can have spontaneous petechiae and bruising. Patients with platelet counts lower than 10,000/mm³ are at risk for internal bleeding, including intracranial hemorrhage (ICH).⁴

ICH is the major cause of mortality in patients with ITP.⁵ The mortality rate of patients with ITP and ICH is greater than 50%.⁶ Atraumatic ICH secondary to ITP is rare, estimated to occur in 0.1% to 1% of patients with ITP. In one report of patients with ICH, 70% had platelet counts lower than 10,000/mm³.⁵ Despite the rarity of this complication, patients with ITP and any cranial or neurologic complaint should be evaluated for ICH.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

Primary and secondary forms of immune-mediated destruction of platelets are recognized. ITP generally refers solely to the primary form of this disease. The secondary form is associated with rheumatic disease, connective tissue disorders, malignant disease, drug exposure, immune deficiencies, and infections, including human immunodeficiency virus infection and hepatitis C. Because no specific diagnostic criteria exist for ITP, it is a diagnosis of exclusion.

The importance of pursuing alternative diagnoses is highlighted by the associated morbidity and mortality of the other diagnoses. The patient’s history can point toward an alternate cause of the thrombocytopenia. Constitutional symptoms such as fever or weight loss suggest malignant disease or infection. Recent initiation of medications such as heparin, clopidogrel, or vancomycin may indicate drug-induced thrombocytopenia.

In ITP the remainder of the laboratory evaluation should be within normal limits. Thrombocytopenia with other abnormalities suggests alternative diagnoses. For example, thrombocytopenia with anemia is found in patients with thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome (HUS). Thrombocytopenia and additional cytopenias are found in leukemia and myelodysplastic disorders. Thrombocytopenia and coagulation abnormalities are found in disseminated intravascular coagulation (DIC).

The peripheral blood smear should be examined. The smear can differentiate true thrombocytopenia from spurious causes of thrombocytopenia such as platelet clumping, platelet satellitism, and abnormally large platelets. Furthermore, the peripheral blood smear can identify manifestations of the primary cause of thrombocytopenia, such as schistocytes in TTP-HUS, evidence of parasitic infections, or findings suggestive of leukemia.

In the patient with suspected ITP, the physician must identify the degree of any bleeding complications. A careful skin examination can quantify the degree of petechiae or bruising. Rectal examination can identify gastrointestinal bleeding. Additionally, any intracranial symptoms, especially in the context of trauma, should be evaluated by computed tomography for possible ICH.

Patients with a history of ITP often have relapses. Most adults with ITP have one or more relapses, commonly during a steroid taper. Relapses are also seen in patients treated with intravenous immune globulin (IVIG) after steroids have failed. Patients with an ITP relapse are treated in the same manner as patients with an initial presentation of ITP. Patients with ITP relapse should also have a nonemergency surgical consultation for possible splenectomy.

**TREATMENT**

ITP is treated by immunomodulation. The first-line treatment is with parenteral steroids. Most patients presenting with ITP
are well and do not need treatment in the ED and can be managed with an early referral to a hematologist. Treatment should be started in patients who are ill, have bleeding complications, need emergency surgery, or have severe thrombocytopenia.

Initiation of treatment should be coordinated with a hematologist, for several reasons. Early leukemia can manifest with isolated thrombocytopenia, especially in pediatric patients. Leukemia should also be considered in adults who have prominent and persistent constitutional symptoms. In a patient who is presenting with leukemia, empiric steroids can lead to alteration of the bone marrow aspirate that causes difficulty and delay in diagnosis.

Steroids are usually started at a dose 1 to 1.5 mg/kg of prednisone per day. IVIG (usual dose of 1 g/kg) is reserved for infants and patients with severe disease or internal bleeding. Anti-D immune globulin is used as an adjunct in Rh-positive patients (usual dose of 75 mcg/kg). Patients with a recurrence of ITP are treated in the same manner as patients with an initial presentation of ITP and should be considered for escalation of therapy. Patients who have chronic or refractory ITP should be considered for splenectomy. The rate of remission of ITP after splenectomy in children is 70% to 80%. The remission rate in adults is unpredictable, ranging from 60% to 70%. Platelet transfusion leads to a rapid but transient increase in platelet count and is therefore indicated only in certain settings, such as in patients with bleeding complications, patients undergoing emergency surgery, and those with severe thrombocytopenia.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

Most patients with suspected ITP are treated and managed as outpatients. However, patients with severe thrombocytopenia—defined as a platelet count lower than 10,000/mm³, patients with head trauma, and those with bleeding complications—should be admitted. Patients should be considered for admission if their platelet count is lower than 30,000/mm³, if they work in a profession (e.g., construction) in which trauma is inevitable, or if the diagnosis is in question. Ultimately, disposition should be based on the patient’s appearance, the severity of thrombocytopenia, concomitant use of antiplatelet agents, and the patient’s access to expeditious follow-up.

Patients who are managed as outpatients should be advised to avoid any antiplatelet agents. Patients, especially children, should limit their activities in situations associated with possible trauma (e.g., construction work, contact sports, gym class). Discharge instructions should instruct patients to return if they have any signs of bleeding, abdominal pain, trauma, or neurologic symptoms.

**THROMBOTIC MICROANGIOPATHIES**

**PERSPECTIVE**

The thrombotic microangiopathies are a group of disorders characterized by intravascular aggregation of platelets that leads to organ ischemia. These disorders include TTP and HUS. Although the two diseases have different names, they share a common mechanism, as well as overlapping clinical features. TTP and HUS are generally believed to lie on a spectrum of disease, as opposed to being distinct clinical entities. Therefore, they are discussed together.

**EPIDEMIOLOGY**

TTP and HUS are rare diseases. TTP has an estimated prevalence of 4 to 11 cases per million people,6 and HUS has an incidence of 1 to 10 cases per 100,000.7 TTP is associated with black race, female sex, and obesity.8 Pregnant and peripartum patients account for 12% to 25% of patients with TTP.9

Despite the rarity, TTP and HUS are associated with significant morbidity and mortality. Untreated TTP has a mortality rate of 90%.10 and adults with typical HUS have a 45% mortality rate.11 Children less than 10 years of age have a 15% chance of developing HUS in the setting of diagnosed *Esch- erichia coli* O157:H7 infection.12 Although 90% of children with typical Shiga toxin–associated HUS recover with supportive care,13,14 they have a 12% rate of death or permanent end-stage renal disease and a 25% incidence of hypertension and proteinuria.13 Shiga toxin–associated HUS is the most common cause of acute renal failure in childhood, and it accounts for 4.5% of pediatric patients who undergo long-term renal replacement therapy.15 Commonly cited risk factors for developing HUS include antibiotic administration, use of antimotility agents, and age younger than 10 years.15

**PATHOPHYSIOLOGY**

The underlying process of the thrombotic microangiopathies is organ dysfunction resulting from intravascular aggregation of platelets that leads to consumptive thrombocytopenia and organ ischemia from thrombosis. The platelet aggregation, in turn, causes mechanical destruction of red blood cells and microangiopathic, nonimmunologic anemia.

In classic HUS, the inciting event is typically an infection with Shiga toxin–releasing bacteria, most commonly *E. coli* O157:H7 and non-O157:H7 subtypes.12 The toxin produced by the bacteria is systemically absorbed, thus leading to widespread microvascular injury and consequent thrombosis. For unknown reasons, most cases of thrombosis in HUS occur in the renal vasculature. Ten percent of cases of HUS are atypical and are not triggered by Shiga toxin.15 The triggers in atypical HUS include pregnancy, autoimmune disorders, drug toxicity, malignant disease, drug reactions, and preceding infections.17

Most patients with TTP have an acquired deficit in the protease ADAMTS-13 that is typically caused by autoantibody destruction. This deficit in ADAMTS-13 leads to the inability to cleave von Willebrand factor multimers and causes intravascular platelet aggregation and thrombosis.14 Genetic susceptibility to the development of TTP has been described but is not well characterized.16 Although most patients with TTP are characterized as having idiopathic TTP, ADAMTS-13 antibodies have also been associated with medications (e.g., quinine, ticlopidine, clopidogrel18,19), pregnancy, autoimmune disorders, direct drug toxicity, and hematopoietic stem cell differentiation.
transplantation. TTP is treated with plasma exchange, which is thought to work by both removing the autoantibodies against ADAMTS-13 and replacing ADAMTS-13 activity.

PRESENTING SIGNS AND SYMPTOMS

The presenting symptoms of both TTP and HUS depend on the severity of the organ dysfunction, the anemia, and the thrombocytopenia. TTP is classically defined by the pentad of thrombocytopenia, anemia, neurologic abnormalities, renal failure, and fever. Fever is typically low grade and is not usually a prominent feature of the syndrome. The neurologic abnormalities in TTP can range from seizures and fluctuating focal deficits to transient confusion. Patients with HUS typically present with signs and symptoms of renal failure including oliguria or anuria, edema, and hypertension. Ninety percent of patients with HUS have typical HUS, with a prodrome of watery diarrhea, which becomes bloody on the third day of illness, that is caused by a Shiga toxin–producing bacterial infection. Despite the distinctions made between TTP and HUS, 25% of patients with HUS can have neurologic abnormalities, and patients with TTP often have renal failure. When both renal impairment and neurologic dysfunction are present, the patient is considered to have TTP if the neurologic abnormalities are prominent and HUS if renal failure is prominent. In both diseases, patients can have symptoms caused by thrombosis and ischemia in any organ, including the heart, bowel, lungs, and pancreas, as well as having symptoms caused by anemia or thrombocytopenia.

Despite the classic descriptions of both TTP and HUS, the most common symptoms are nonspecific. Patient typically present with complaints of abdominal pain, nausea, vomiting, and weakness and are frequently misdiagnosed as having gastroenteritis, sepsis, or transient ischemic attack. Even when the diagnosis is made, 10% of patients with an initial diagnosis of TTP in one report were eventually found to have sepsis or systemic cancer.

DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Making the diagnosis of TTP-HUS is challenging. Clinical suspicion is essential. The diagnosis is clinical, with no “gold standard” findings, and the signs and symptoms can be subtle, especially early in the disorder. These are also rare conditions that have clinical overlap with sepsis and DIC. The importance of making the diagnosis is emphasized by the 90% mortality rate of TTP and the knowledge that plasma exchange is a curative treatment.

Several elements of the patient’s history should alert the clinician to the possibility of TTP-HUS. HUS should be considered in children with symptoms of renal failure after a diarrheal illness. TTP should be considered in patients presenting after initiating antiplatelet agents, especially in the first 3 to 14 days. Although TTP is considered an acute illness, one fourth of patients report symptoms for several weeks before diagnosis.

TTP has been described in patients of all ages, but it is seen primarily in adults. The diagnosis of TTP should be considered in any patient with thrombocytopenia and anemia without a readily apparent cause. The anemia of TTP is microangiopathic hemolytic anemia, which is associated with schistocytes and elevated lactate dehydrogenase levels. The hemolysis is nonimmunologic and therefore should elicit a negative Coombs test result. The dyad of thrombocytopenia and microangiopathic hemolytic anemia, with or without renal or neurologic abnormalities, is sufficient to establish the diagnosis of TTP and to start plasma exchange. Additional signs of hemolysis include elevated serum lactate dehydrogenase levels secondary to red blood cell fragmentation and organ ischemia, an elevated reticulocyte count, and low haptoglobin levels. These patients should have no coagulation abnormalities.

Because of the clinical overlap and the divergent treatment of sepsis, DIC, and TTP-HUS, the physician should focus on the distinguishing features. Fever is part of the pentad of TTP but tends to be low grade. High fevers, associated with rigors, or the identification of an infectious source, point toward sepsis. A new coagulation abnormality suggests DIC as the cause of thrombocytopenia and anemia.

Pregnant and peripartum patients with suspected TTP are a diagnostic and clinical challenge. Pregnant patients account for a large percentage of cases of TTP, and clinical overlap exists between TTP and preeclampsia-HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. Clinically, the two diseases have vastly divergent treatment. Patients with TTP and preeclampsia-HELLP have thrombocytopenia, microangiopathic anemia, renal disease, and neurologic abnormalities. Both diseases are seen primarily in the second and third trimesters. Distinguishing features include more severe hypertension in preeclampsia. The renal dysfunction in patients with preeclampsia is typically proteinuria, compared with the frank renal failure and oliguria seen in TTP-HUS. The thrombocytopenia in preeclampsia tends to be milder and corrects rapidly after delivery. The neurologic abnormalities in preeclampsia are typically headache, scotoma, and seizure, unlike the cerebrovascular accident or mental status change seen in TTP. Pregnant patients with possible TTP should have care coordinated among obstetrics, hematology, and nephrology.

Examination of the peripheral blood smear can be useful in patients with suspected TTP-HUS. In addition to identifying schistocytes, it can differentiate true thrombocytopenia from spurious causes of thrombocytopenia, as well as identifying alternative diagnoses such as leukemia. Hematology and nephrology should be involved in these cases to coordinate plasma exchange and dialysis.

TREATMENT

The treatment for TTP is plasma exchange. Plasma exchange halts the thrombosis by removing the autoantibodies against ADAMTS-13 and replacing the ADAMTS-13. Plasma exchange should start within 24 hours of presentation. If plasma exchange is not available or will be severely delayed, plasma infusion at 30 mL/kg/day may be attempted. Immunosuppression with glucocorticoids is used as an adjunct in patients with idiopathic ITP and in patients who have exacerbations after plasma exchange is stopped or in patients who have a relapse after remission. The dose of prednisone is 1 to 2 mg/kg/day. Some weak evidence indicates that additional
immunosuppression with cyclophosphamide or vincristine may be beneficial, but it is not routinely recommended. When clopidogrel or ticlodipine is the suspected cause, the medication must be discontinued.

The treatment of HUS varies among patient populations. The treatment of children with typical Shiga toxin–associated HUS centers around aggressive supportive care, including fluid and electrolyte management, blood pressure management, red blood cell transfusion, and dialysis when indicated. Plasma exchange or plasma infusion is not routinely indicated for the treatment of typical HUS. Plasma exchange should be considered in patients with HUS that is not associated with Shiga toxin–associated diarrhea, in adults, in patients with neurologic abnormalities, and in those who are very ill.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

All patients with TTP-HUS should be admitted to the hospital for further management. Even if patients appear well, TTP has no outpatient management. Patients with HUS need electrolyte and fluid management. Patients should be admitted to telemetry beds because of the possibility of myocardial ischemia.

Patients should be educated about the possibility of long-term sequelae, including renal failure, permanent neurologic disability, and myocardial dysfunction, as well as the possibility of relapse. The long-term prognosis depends on various factors, including age, degree of organ dysfunction, prompt treatment with plasma exchange, and length of time undergoing dialysis. Children universally do better than adults. Young children with typical (Shiga toxin diarrhea–associated) HUS have the best prognosis of all patients with TTP-HUS. Patients with typical HUS are unlikely to have a recurrence, whereas patients with idiopathic TTP have a 50% relapse rate.

**EPIDEMIOLOGY**

The diagnosis of drug-induced thrombocytopenia is challenging. More than 150 drugs have been implicated (Box 205.2), but the epidemiology is not well characterized because of the dual lack of consistent, high-quality reporting and diagnostic criteria. This rare disease has an estimated incidence of 10 cases per 1,000,000 patients, but it occurs more frequently in hospitalized patients and in older persons. Reported incidences of thrombocytopenia induced by specific medications have ranged from 0.0003% with quinine to 1% with gold salts and abciximab. This diagnosis is important to consider because the only effective treatment is discontinuation of the medication. Drug-induced thrombocytopenia does not respond to immunomodulation, as do conditions such as ITP.

Heparin-induced thrombocytopenia (HIT) must be considered separately from all other forms of drug-induced thrombocytopenia. HIT is more common than other drug-induced thrombocytopenias, with an incidence as high as 5% in high-risk populations. Additionally, it has a much higher rate of both morbidity and mortality from thrombotic complications, which can persist after the heparin is discontinued and platelet levels return to normal. The risk of developing thrombocytopenia is 10 times higher in patients who are exposed to unfractionated heparin, when compared with those receiving low-molecular-weight heparin.

**PATHOPHYSIOLOGY**

In drug-induced thrombocytopenia, the drop in platelets is an immunologic process. The drugs themselves are not immunogenic. When the drug is bound to the platelet, however, the drug–platelet complex induces antibody production. The key feature of most of these antibodies is that they are not true autoantibodies because they do not bind to the platelet if the drug is not bound. Very rarely, drugs can induce true autoantibodies that can bind to the platelet in the absence of the drug. This phenomenon is most commonly seen during treatment with gold salts, but it also occurs with procainamide, sulfonamides, and interferon-α and -β.

Binding of the antibodies to the platelet or the platelet-drug complex leads to immune destruction of the platelet and thrombocytopenia through the reticuloendothelial system, primarily in the spleen. In addition to the immune destruction of the platelets, the antibodies in HIT lead to platelet activation, which causes thrombosis.

**PRESENTING SIGNS AND SYMPTOMS**

Most patients with drug-induced thrombocytopenia, including HIT, are asymptomatic. Patients presenting with bleeding complications are common in platelet dysfunction. These complications include findings such as petechiae, easy bruising, epistaxis, and other mucocutaneous bleeding. The typical time course is 5 to 7 days after exposure to a new medication. Patients previously sensitized to a medication can have a dramatic and rapid drop in platelets. The development of HIT can, in rare circumstances, be remote from the drug exposure.

</tbody>
</table>

In contrast to the other type of drug-induced thrombocytopenia, 20% to 50% of patients with HIT present with thrombotic complications. Of these thromboses, 70% are venous, and 30% are arterial.25 The clinical presentation of patients with thrombotic complications from HIT depends on the vascular bed that is involved. The venous thromboses are most commonly deep vein thromboses and pulmonary emboli, but they also include cerebral and adrenal venous thromboses. The arterial thromboses are reported in the limbs, aorta, cerebral, and coronary vasculatures.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The thrombocytopenia of HIT can either be absolute (<150,000/mm³) or relative (decrease of >50% from baseline.) Patients almost universally have detectable levels of antibodies against platelet factor 4. Other drugs with drug-induced thrombocytopenia do not have readily available testing for drug-platelet antibodies.

Because immunologic testing is not often available or available in a timely fashion, the diagnosis and initial management must often be empiric. Drug-induced thrombocytopenia should resolve within several days of discontinuation of the medication.

**TREATMENT**

The most important therapeutic intervention is discontinuation of the offending medication. Most of these antibodies have activity against the platelets only when the drug is bound, thus stressing the importance of identification and discontinuation of the drug. In most patients, the thrombocytopenia resolves without further intervention.

Patients with severe thrombocytopenia or bleeding should be treated with platelet transfusion. Immunomodulating medications such as corticosteroids, IVIG, and plasma transfusion have been tried, without any conclusive evidence supporting their efficacy.22

Patients with thromboses from HIT must be treated with direct thrombin inhibitors (e.g., lepirudin, argatroban, bivalirudin). When choosing among these medications, the physician must consider that lepirudin and bivalirudin are renally excreted, whereas argatroban is hepatically metabolized. This distinction is especially important because of the high rate of iatrogenic bleeding complications. Furthermore, because lepirudin is highly immunogenic, patients with recurrent HIT should not be treated with lepirudin more than once. Warfarin monotherapy in active HIT is contraindicated, but warfarin may be started in patients with platelet counts higher than 150,000/mm³ and therapeutic levels of anticoagulation. Care should be taken to remove all sources of heparin, including catheter ports and dialysis tubing.

**FOLLOW-UP, NEXT STEPS OF CARE, AND PATIENT EDUCATION**

The determination of disposition of a patient with suspected drug-induced thrombocytopenia should start with a search for other conditions that cause thrombocytopenia, most importantly sepsis. Next, the implications of discontinuing the medication and the question whether an acceptable alternative exists must be considered. Patients treated as outpatients should have urgent follow-up to evaluate for signs of bleeding and serial blood counts to ensure the resolution of the thrombocytopenia.

**THROMBOCYTOSIS**

**EPIDEMIOLOGY**

Thrombocytosis is usually an incidental finding in a patient in the ED. Most patients have secondary thrombocytosis, from an acute or chronic condition such as infection or malignant disease. Even in the extremes of thrombocytosis with platelet counts greater than 1,000,000/mm³, 88% of patients have reactive thrombocytosis.26

The other main cause of thrombocytosis is essential thrombocythemia (ET), which is one of the myeloproliferative disorders. ET is a relatively rare disease with an estimated incidence of 2.5 cases per 100,000 patients.27 In contrast to reactive thrombocytosis, patients with ET are prone to both bleeding and thrombotic complications.

**PATHOPHYSIOLOGY**

Platelet production and homeostasis are primarily controlled by the effects of thrombopoietin on the megakaryocytes. Thrombocytosis can either be primary or secondary. In primary thrombocytopenia (ET), the thrombocytosis results from the clonal proliferation of megakaryocytes. Secondary thrombocytosis is caused by the effects of various catechols and cytokines,28 as well as increased production of thrombopoietin in the liver in response to inflammatory stimuli.29

**PRESENTING SIGNS AND SYMPTOMS**

Thrombocytosis is typically an incidental finding. Because most patients with thrombocytosis have secondary thrombocytosis, the presenting symptoms relate to the underlying condition and not to the thrombocytosis itself. The underlying conditions can be transient or sustained. Secondary thrombocytosis can be caused by a clinically occult process such as malignant disease or a chronic inflammatory condition. Patients with secondary thrombocytosis do not have any thrombotic or bleeding sequelae even in the extremes of thrombocytopenia unless it is a sequel of the underlying disorder.

Patients with ET can present with both bleeding and thrombotic complications. Thrombotic complications are more common that bleeding complications, with a ratio of 11:1, and arterial thrombosis is more common than venous thrombosis, with a ratio of 3:1.30

The bleeding complications are similar to those seen with thrombocytopenia and qualitative platelet disorders. Findings may include petechiae, hematuria, and gastrointestinal bleeding. Counterintuitively, these bleeding complications are more likely to occur in the extremes of thrombocytosis.28
The thrombotic complications of ET are common. Fifty percent of patients with ET have at least one thrombotic complication in the first 9 years from diagnosis.30 The thrombotic complications have an unusual distribution. In addition to deep vein thromboses, patients are at risk for developing venous thromboses of the cerebral, hepatic, and portal veins. Most arterial complications are cerebrovascular, accounting for symptoms ranging from migraine-like symptoms to transient ischemic attack and stroke.30,31 Despite its relative rarity, ET is classically associated with digital ischemia and erythromelalgia, which is characterized by patchy burning or throbbing pain in the extremities. Associated skin findings range from mottling to erythema, to absent. Erythromelalgia can progress to gangrene and necrosis if it is not treated. In addition, patients with ET are at extreme risk for pregnancy-related complications, including fetal growth retardation and recurrent spontaneous abortions, because of placental thromboses.

Differential Diagnosis and Medical Decision Making

No known signs, symptoms, or laboratory findings distinguish ET from secondary thrombocytosis. Because of the lack of diagnostic criteria, ET is a diagnosis of exclusion, and the initial diagnosis and treatment should be focused on excluding an underlying cause of secondary thrombocytosis. ET can be secondary to acute and chronic conditions, medication reactions, stress, and clinically occult conditions. Tests such as C-reactive protein and erythrocyte sedimentation rate, as well as fecal occult blood testing, can point toward an underlying inflammatory or malignant condition.

The main differentiating feature between secondary and ET is that secondary thrombocytosis does not have associated thrombotic or bleeding complications attributable to the thrombocytosis. Even so, that primary disease process can put the patient at increased risk for both thrombotic and bleeding sequelae. Patients with ET are at risk for spontaneous transformation of the disorder into acute leukemia. The main clue to leukemic transformation is involvement of multiple cell lines.

Treatment

Treatment of ET depends on the presentation. Patients with ET are commonly receiving a combination of aspirin and cytoreductive therapy. Typical agents include hydroxyurea, anagrelide, or interferon-α. Hydroxyurea is teratogenic, and the safety of interferon-α in pregnancy is not known, so patients with ET and newly diagnosed pregnancy should be counseled appropriately.

Patients with symptomatic ET must be treated aggressively. Patients with arterial thrombotic complications should have a combination of aspirin and cytoreductive therapy with hydroxyurea, anagrelide, or interferon-α. In addition, patients should be considered for platelet pheresis especially if they have cerebral and digital ischemia.28 ED initiation of treatment for asymptomatic patients with suspected ET is not indicated. Patients should be referred to hematology and to their primary care physician for further evaluation.

Patients with secondary thrombocytosis do not need any specific treatment for the thrombocytosis. Diagnostic work-up and treatment should all be directed toward the underlying condition.

Follow-Up, Next Steps of Care, and Patient Education

Patients with known ET with either thrombotic or hemorrhagic complications should be admitted. Patients with asymptomatic thrombocytosis that has no clear underlying cause can be treated as outpatients, with coordination with their physicians and a hematologist. Patients with suspected ET should be instructed to return to the ED for any neurologic complaints or unexplained burning or throbbing pain in the extremities or bleeding.

Bleeding Disorders

Michael Levine and Joshua N. Goldstein

KEY POINTS

- Bleeding disorders are common and can be classified as congenital or acquired.
- A thorough history, including medication history, can help screen for many potential bleeding disorders.
- The prothrombin time is a measurement of abnormalities in the tissue factor pathway, whereas the activated partial thromboplastin time is a measurement of abnormalities in the contact activation pathway.
- Hemophilia A and B are both X-linked conditions, and factor replacement may be needed as prophylaxis or treatment for bleeding. Recombinant factor VIIIa can be used to treat patients with inhibitors.
- von Willebrand disease is the most common congenital bleeding disorder. Treatment options vary, depending on the severity of the condition and bleeding, but they include desmopressin, aminocaproic acid, tranexamic acid, and factor replacement.
- Common causes of acquired coagulopathies include trauma, massive transfusion, disseminated intravascular coagulation, drugs, and toxins.
- The definitive treatment of disseminated intravascular coagulation is reversal or treatment of the underlying cause.

EPIDEMIOLOGY

Under normal physiologic conditions, a constant balance exists between clot formation and clot breakdown, with a preference favoring anticoagulation. Hemostasis results from a complex interaction among the vascular endothelium, platelets, the coagulation cascade, and the fibrinolytic system. Any disorder that affects this interplay can alter the equilibrium, thereby producing either excessive thrombosis or excessive hemorrhage.

Broadly speaking, bleeding disorders can be either inherited or acquired. Of the inherited disorders, the von Willebrand syndromes and hemophilia A are the most common, with a prevalence between 1 per 100 individuals and 1 per 100,000 individuals. Less common inherited disorders include deficiencies of factors II, V, VII, X, XIII, and fibrinogen, with a prevalence between 1 and 2 per 100,000 individuals. The most common acquired bleeding disorders are drug induced, from therapeutic administration of agents expressly intended to decrease the risk of thrombosis. Oral anticoagulants are taken by up to 2% of the population and up to 8% of persons more than 65 years old, and the use of antiplatelet agents is vastly more common than that. Patients with inherited bleeding disorders will likely present to the emergency department (ED) for treatment of abnormal bleeding at some point during their lifetime, and ED visits for bleeding in patients who are taking antithrombotic agents are not uncommon. The clinician must be familiar with these disease states to provide prompt care because treatment delays can increase morbidity and mortality.

PHYSIOLOGY AND BIOLOGY OF HEMOSTASIS

COAGULATION CASCADE

The coagulation cascade (Fig. 206.1) is typically thought of as two pathways working separately. In reality, however, the tissue factor pathway (formerly called the extrinsic system) and the contact activation pathway (formerly called the intrinsic system) function intimately with each other to produce thrombin, a critical enzyme in the coagulation system.

Tissue factor typically resides on smooth muscle cells, fibroblasts, and pericytes. Binding of tissue factor to factor VII results in an activated factor VII (factor VIIa). Factor VIIa subsequently catalyzes the conversion of factors IX and X to their active forms (factors IXa and Xa, respectively).

The contact activation pathway begins with the activation of factor XII by the high-molecular-weight enzymes kininogen and prekallikrein. This activation subsequently triggers a series of reactions leading to the conversion of X to Xa, the first step of the common pathway. The exact relevance of the contact activation pathway is debatable, however, because its activation is not needed in trauma-initiated coagulopathy. Furthermore, with the exception of a deficiency of factor XI, deficiencies in enzymes involved in the contact activation pathway generally do not produce substantial coagulopathies.

The common pathway starts with the conversion of factor X to Xa, which, in turn, converts prothrombin to thrombin. Ultimately, thrombin catalyzes the conversion of fibrinogen to fibrin.

PLATELET FUNCTION

Following injury to the vascular endothelium, endothelin is released, resulting in vasoconstriction. In addition, injury to the vascular endothelium results in tissue factor exposure, with subsequent binding of platelets to the endothelium. Platelet adhesion primarily involves the binding of platelets to damaged endothelium by von Willebrand factor (vWF). Additional platelet activation occurs through the release of numerous mediators including adenosine diphosphate (ADP), epinephrine, thromboxane A2, and thrombin. Ultimately,
Coagulation cascade.

Platelet activation and aggregation require glycoprotein IIb/IIIa. Thrombus stability, however, requires fibrin, which is formed from the coagulation cascade on the surface of platelets.

**PRESENTING SIGNS AND SYMPTOMS**

The optimal management of the patient with a bleeding disorder involves, as always, aggressive resuscitative measures (e.g., focus on ensuring adequate airway, breathing, and circulation). However, those patients with bleeding disorders also require specific therapies targeted toward the underlying disease state. Diagnostic laboratory tests and factor or product replacement should be administered on an individualized basis.

A careful history must be obtained from the patient, including the exact nature of the bleeding disorder, if known. A history regarding xenobiotic usage and past bleeding episodes should be obtained, including a history of previous bleeding with mild procedures (e.g., prolonged bleeding following tooth extractions), menstrual history (e.g., particular heavy with mild procedures), and prior transfusion history. In addition, the clinician should question the patient regarding current bleeding, including the presence of dermal (petechiae, purpura, or ecchymosis), gastrointestinal (melena, hematochezia, or hematemesis), genitourinary (hematuria), mucosal membrane (gingival or epistaxis), and musculoskeletal (hemarthrosis) hemorrhage.

**DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING**

The initial assessment of a patient with a known or suspected bleeding disorder begins with a thorough history and physical examination. Laboratory studies can be used to assess the severity of the disorder and to support a diagnosis. The initial laboratory studies that should be obtained when evaluating such patients include a complete blood count, prothrombin time (PT; a measure of the tissue factor pathway), and an activated partial thromboplastin time (aPTT; a measure of the contact activation pathway). A fibrinogen count can also assist in the initial management. These laboratory tests can help screen for clinically significant factor deficiencies, such as hemophilia A or B, as well as hypofibrinogenemic states. Additional tests may be indicated, depending on the condition of interest. For example, the concentration of D-dimers may be helpful in establishing the diagnosis of disseminated coagulation (DIC), whereas factor concentrations may be useful in assessing the severity of hemophilia. Patients with acute fulminant hepatic failure may demonstrate abnormalities similar to those seen in DIC. In such cases, factor V, VII, and VIII levels can be obtained. Although factor V levels are likely to be decreased in both DIC and liver failure, factor VIII levels are normal or elevated in liver failure—induced coagulopathy, yet markedly decreased in DIC-induced coagulopathy. Factor VII levels are also reduced in coagulopathy resulting from hepatic failure. Mixing studies can be performed to determine whether a factor deficiency or inhibitor is present in patients with prolonged aPTT. Examination of the peripheral blood film can be very helpful in patients with unexplained bleeding disorders.

**COAGULATION CASCADE DEFECTS**

Platelet-related defects are discussed in Chapter 205.

**HEREDITARY DEFECTS**

**Hemophilia A and B**

Hemophilia A and hemophilia B are X-linked recessive disorders involving factors VIII and IX, respectively. Clinically, hemophilia B is indistinguishable from hemophilia A. However, nearly half of all cases of hemophilia A, the most common form of hemophilia, represent de novo mutations, in which boys are born to parents without the disease. These disorders can be classified as mild, moderate, or severe, corresponding to a plasma coagulation factor concentration of 6% to 30%, 2% to 5%, or 1% or lower, respectively. Those patients with a mild form of the disease generally have bleeding only after trauma or surgery. In contrast, patients with the severe form of the disease have an average of 20 to 30 bleeding episodes annually, and bleeding occurs spontaneously or after minor trauma. Hemarthrosis is one of the most common forms of bleeding in severe forms of hemophilia. Historically, treatment involved transfusions of plasma concentrates of coagulation factors. However, such an approach was associated with the acquisition of numerous infectious diseases, including human immunodeficiency virus infection or hepatitis, as well as the development of inhibitors to the clotting factors. Now, both plasma and recombinant-derived factor VIII and IX exist. Treatment can be administered as an on-demand regimen, in which therapy is given based on bleeding, or in a prophylactic regimen. Because the plasma half-life of factor IX is longer than of factor VIII (18 to 24 hours versus 8 to 12 hours), dosing of factor replacement is less frequent for hemophilia B than for hemophilia A.

*Many etiologies of coagulopathy do not require factor replacement or transfusion. If these products are to be administered, the specific agent is listed in the table. However, for many conditions, no blood product should be transfused. The text can help guide when specific therapies should be administered.

†Where licensed.

**DDAVP, Desmopressin; FFP, fresh frozen plasma; PCC, pool complex concentrates.**

Table 206.1 shows a common treatment regimen. Minor bleeding requires factor replacement to achieve factor concentrations of 30% of normal (typically 30 units/kg). In contrast, major hemorrhagic events, including hemarthrosis and large muscle bleeding, requires factor replacement to achieve factor concentrations of at least 50% (typically 50 units/kg). Life-threatening hemorrhage requires factor replacement to achieve factor concentrations of at least 80% (typically 80 units/kg). In general, each unit per kilogram of body weight of factor VIII increases plasma factor VIII concentrations by 2%, whereas each unit per kilogram of body weight of factor IX increases plasma factor IX concentrations by 1%. In patients with life-threatening bleeding, however, in vivo factor concentrations should be followed to ensure adequate replacement. When patients with hemophilia A have developed inhibitors to factor VIII, recombinant factor VIIa (rFVIIa) (90 mcg/kg) has been used.

**von Willebrand Disease**

von Willebrand disease (VWD) is the most common hereditary bleeding disorder. Although laboratory evidence of this disorder is present in up to 2% of the population, clinically relevant bleeding occurs much less commonly. vWF has two roles in maintaining hemostasis. First, vWF forms a link between platelets and the vascular endothelium of injured blood vessels. Second, vWF serves as a plasma carrier for...
factor VIII. The primary defect in VWD is a quantitative deficiency (types I, III) or a qualitative defect (type II) in vWF. However, because vWF serves as a plasma carrier and stabilizer for factor VIII, VWD is also associated with a secondary decrease in factor VIII.

Mucocutaneous bleeding is the most common clinical manifestation of VWD. Epistaxis, hematomas, and menorrhagia are relatively common. Patients with type III disease, the most severe form, develop spontaneous hemorrhaxis resembling that seen in hemophilia. The diagnosis can be confirmed by obtaining a vWF antigen, vWF ristocetin cofactor assay, and factor VIII activity. Minor bleeding, including mucosal bleeding, usually does not warrant specific treatment. For more severe bleeding, however, antifibrinolytic agents and desmopressin should be administered (see Table 206.1). Desmopressin produces a transient increase in factor VIII and vWF three to five times higher than baseline within 1 hour of intravenous administration, and it should be administered at a dose of 0.3 mcg/kg intravenously. Antifibrinolytic agents include amicar (50 to 60 mg/kg every 4 to 6 hours) and tranexamic acid (10 to 15 mg/kg every 8 to 12 hours). For those patients with life-threatening bleeding, factor VIII and vWF concentrates may be needed.

Miscellaneous Factor Deficiencies
Numerous other congenital coagulation factor deficiencies are recognized. Defects in factor V can result in either hemorhagic or thrombotic complications. Factor V deficiencies can be classified as either type I (low or unmeasurable antigen level) or type II (normal or mildly low antigen level). Parahemophilia, a severe form of the type I variety, is generally associated with mild bleeding. No factor V–specific concentrate is available, so bleeding, if it occurs, should be treated with fresh frozen plasma (FFP) (see Table 206.1).

Factor X, a vitamin K–dependent clotting factor, is the first enzyme in the common pathway in the coagulation cascade. Factor X deficiency is one of the rarest inherited coagulation disorders. Patients with severe deficiency usually develop hemorrhage early in life, including umbilical stump bleeding. Patients with less severe deficiency, in contrast, typically develop bleeding only following trauma or menorrhagia, for example. In addition to congenital deficiencies, several states are associated with acquired factor X deficiency, including liver disease, vitamin K deficiency, myeloma, and various malignant diseases. In addition, the AL, but not the AA, form of amyloidosis has been associated with acquired factor X deficiency. Sodium valproate use is associated with a transient form of factor X deficiency. If bleeding occurs, the patient should receive FFP or prothrombin complex concentrates (PCC) (see Table 206.1). A deficiency of either factor XI or factor XII (Hageman trait) is rarely associated with clinically relevant bleeding. Severe forms of factor XI deficiency can be clinically relevant, however, and bleeding is best treated with the administration of FFP (see Table 206.1). Factor XI is more common among individuals of Ashkenazi heritage.

Congenital Fibrinogen Disorders
Congenital fibrinogen disorders include hypofibrinogenemia and afibrinogenemia. Patients frequently present at birth with umbilical stump bleeding. In older individuals, life-threatening bleeding is rare, but it can include gastrointestinal hemorrhages and central nervous system bleeding. In contrast to patients with various factor deficiencies, patients with fibrinogen defects typically do not have significant spontaneous bleeding, and when bleeding does occur, it is typically less severe and primarily associated with trauma or surgery. Fibrinogen deficiency can be treated with FFP, cryoprecipitate, or (where licensed) fibrinogen concentrates (see Table 206.1).

ACQUIRED DEFECTS

Drugs
Numerous pharmaceutical agents can produce coagulopathy by interfering with the coagulation cascade at various levels. Furthermore, salicylates, ADP antagonists (e.g., ticlopidine, clopidogrel, prasugrel, and ticagrelor), and glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban) can result in hemorrhage, but they induce platelet dysfunction, rather than disorders in fibrin formation. In addition, innumerable drugs can cause thrombocytopenia with prolonged use. Drugs that alter platelet function are discussed elsewhere (see Chapter 205).

Warfarin is a vitamin K antagonist, which inhibits the cyclic conversion of vitamin K 2,3-epoxide to vitamin K quinone, as well as the conversion of vitamin K quinone to the active form of vitamin K, vitamin K quinol. The inhibition of these enzymes prevents the γ-carboxylation of the vitamin K–dependent clotting factors, namely, factors II, VII, IX, and X, along with protein C and protein S. Patients taking warfarin frequently present to the ED either because of a supratherapeutic international normalized ratio (INR), which was checked during an outpatient visit, or because of hemorrhage. The treatment of an elevated INR depends on the clinical circumstances. For example, if a patient is asymptomatic but has an incidental INR of 4, simply withholding a dose of warfarin may be appropriate, whereas a patient with an intracranial hemorrhage with an INR of 2 requires aggressive reversal. Table 206.2 outlines the recommended guidelines for warfarin reversal. In general, if vitamin K is to be administered, oral and intravenous routes are preferred because subcutaneous and intramuscular administration leads to poor and erratic absorption.

Heparin products can be classified as either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). Commonly used LMWHs include dalteparin, enoxaparin, tinzaparin, and ardeparin. Traditionally, UFH was the primary xenobiotic used for both prophylaxis and treatment of venothromboembolic disease. However, because of increased ease of administration, a lack of need for laboratory monitoring, and a more predictable dose-response curve, the use of LMWH has substantially increased. UFH produces anticoagulation by binding to antithrombin III, thereby producing a conformational change. The modified antithrombin III–heparin complex is a potent inhibitor of factors IIa and Xa. UFH also has some activity against factors IXa, XIIa, and kallikrein. The LMWHs, in contrast, also bind to antithrombin III, but they have greater effect on factor Xa. Comparing the LMWHs with UFH, the LMWHs have a higher ratio of antifactor Xa to IIa than does UFH.

The anticoagulant effects of heparin are measured by following the aPTT. Monitoring is typically not needed for the LMWHs. However, if monitoring is desired, an antifactor Xa level should be obtained 4 hours after subcutaneous

Injection. Heparin reversal is accomplished by the intravenous administration of protamine sulfate (see Table 206.1). Each unit of protamine sulfate reverses 100 units of UFH. Because protamine sulfate primarily reverses factor Xa, and not Xa, its use in patients with LMWH produces only a partial reversal.

Factor Xa inhibitors can inhibit factor Xa either indirectly (idraparinux or fondaparinux) or directly (rivaroxaban). Unlike the LMWH agents, which inhibit both factors IIa and Xa, the factor Xa inhibitors produce no inhibition of factor IIa. Rivaroxaban, which is available orally, is considered a direct factor Xa inhibitor because it binds directly to factor X, unlike idraparinux and fondaparinux, which bind to antithrombin III. In the event of life-threatening hemorrhage in patients taking a factor Xa inhibitor, no consensus on therapy exists, although some investigators have recommended rFVIIa for this purpose. Outcome data are insufficient to recommend the routine administration of rFVIIa for the reversal of factor Xa inhibitors; the use of rFVIIa for this purpose must be weighed against the potential for thromboembolic events.

### Coagulopathy of Trauma

Coagulopathy is common among trauma patients. Nearly 25% of critically ill trauma patients are found to have some laboratory or clinical evidence of coagulopathy on admission. This coagulopathy is related to injury severity but not to fluid resuscitation. Coagulopathy, along with hypothermia and acidosis, is part of the “triad of death” because its development produces synergistic effects that can ultimately culminate in mortality.

The mechanism by which this process occurs is unclear. First, local tissue damage after trauma is thought to result in exposure to tissue factor from the damaged endothelium, thereby activating the coagulation cascade. In addition, traumatic brain injury results in the release of brain-specific thromboplastins, leading to consumption of clotting factors. Finally, severely injured trauma patients can present in shock. This leads to diffuse endothelial disruption and early production of factors II, V, VIII, and X. Furthermore, shock results in decreased clearance of thrombin, thereby leading to activation of protein C with resultant inactivation of factors Va, VIIIa, and plasminogen activator inhibitor-1. Acidemia alters coagulation protease function, increases fibrinogen degradation, and further contributing to coagulopathy. Hypothermia, which is common in trauma patients, results in coagulopathy secondary to decreased activity of factor VIIa, inhibition of coagulation protease activity, and impaired platelet function.

Treatment of patients with trauma-induced coagulopathy begins with basic resuscitation, including the removal of wet clothes, as well as the application of warmed blankets, warmed fluids, and maintenance of high ambient heat. Coagulopathy can be treated with FFP (see Table 206.1). In the setting of acute blood loss, platelet transfusions can be given to maintain a platelet count of at least 50 × 10^9/L. rFVIIa has been used on an off-label basis in numerous studies as a treatment of trauma-induced coagulopathy. Although the use of rFVIIa may be associated with reduced transfusion of blood products, no effect on outcome has yet been demonstrated. Its use must be weighed against its associated cost, lack of clear proven benefit, and potential for thromboembolic complications.

### Transfusion-Related Coagulopathy

The administration of large volumes of fluids to actively bleeding patients can lead to a dilution of clotting factors and platelets that contributes to coagulopathy. Furthermore, the aggressive use of colloids (e.g., hydroxyethyl starch) is associated with migration of plasma proteins to the interstitial space, with a resulting reduction of plasma concentrations of factors VII and vWF, as well as impaired platelet function. The liberal use of crystalloid fluids, especially lactated Ringer
solution with racemic lactate, is associated with a significant increase in immune mediators.\textsuperscript{54} 

The term \textit{massive transfusion} commonly refers to the replacement of one’s blood volume within 24 hours, or the replacement of 50\% of the total blood volume within 3 hours.\textsuperscript{45} The transfusion of large volumes of packed red blood cells (PRBCs), as occurs during a massive transfusion, is associated with numerous complications, including coagulopathy.\textsuperscript{56} In the military setting, the use of massive transfusion protocols has been associated with improved survival. In the civilian trauma setting, however, mortality benefit from such protocols is conflicting. An example of such a protocol includes a set transfusion ratio of FFP to PRBCs of 1 : 2 or 1 : 1.\textsuperscript{41,47,48} Many protocols also include platelets, which are transfused at a ratio of FFP to platelets of 1 : 1 : 1.

\textbf{Toxin} 

Pit vipers include rattlesnakes, copperheads, and cottonmouths. Pit viper envenomations, especially those from rattlesnakes, can lead to local pain and edema, myotoxicity, and hematotoxicity. Initial evaluation of these patients should include a complete blood count, fibrinogen, and prothrombin time. Thrombocytopenia, hypofibrinogenemia, and coagulopathy can develop quickly after an envenomation. Because the venom does not result in thrombin production, fibrin is not cross-linked. This lack of thrombin production and fibrin cross-linkage separates crotalid-induced coagulopathy from true DIC.\textsuperscript{59} Afibrinogenemia, which can occur following envenomation, is not a result of a consumptive coagulopathy, but rather of primary fibrinogenolysis.\textsuperscript{56} Furthermore, despite profoundly abnormal laboratory findings, because the patient is able to produce endogenous thrombin, hemostasis remains intact, and gross hemorrhage remains rare.\textsuperscript{49}

Treatment of pit viper–induced coagulopathy and thrombocytopenia is with antivenom. Crotalidae polyvalent immune Fab (ovine) (CroFab) is the only available antivenom currently approved for the management of pit viper envenomation in the United States. A full review of pit viper envenomations is beyond the scope of this chapter, but in general, stable patients should receive an initial dose of four to six vials intravenously over 1 hour.\textsuperscript{51} In the absence of life-threatening hemorrhage, blood products are not indicated, despite the presence of critically abnormal platelets, PT, or fibrinogen.\textsuperscript{52}

Following therapy with CroFab for rattlesnake envenomation, late hematotoxicity can occur. Patients can develop recurrence, in which severe thrombocytopenia or coagulopathy can occur days after therapy, even if these laboratory abnormalities were not initially present. Thus, these patients should have a fibrinogen, PT, and complete blood count assessed 2 to 4 days and again 5 to 7 days after envenomation.\textsuperscript{51,53}

\textbf{Disseminated Intravascular Coagulation} 

In the setting of severe systemic illness or injury, the body’s coagulation processes can become activated, thereby resulting in widespread, excessive microvascular thrombosis. This thrombosis can result in impaired end-organ perfusion that contributes to multisystem organ failure. Because of this extreme, disproportionate activation of the coagulation system, consumptive coagulopathy can occur, in which platelets, clotting factors, and protease inhibitors are consumed. Intravascular fibrin strand formation results in the shearing of red blood cells, with subsequent development of microangiopathic hemolytic anemia.\textsuperscript{54} Thus, this condition, DIC, results in excessive clot formation, bleeding, or both simultaneously.\textsuperscript{53} DIC does not occur as a primary process but is always secondary to some underlying disorder, including sepsis, trauma, malignant disease (particularly metastatic adenocarcinoma, acute promyelocytic leukemia), tumor lysis syndrome, and obstetric conditions (e.g., abruptio placenta, placenta previa, amniotic fluid embolism, HELLP [hemolysis, elevated liver enzymes, low platelets] syndrome, uterine atony), among others.\textsuperscript{54,56}

DIC can be considered either acute or chronic.\textsuperscript{54} The diagnosis of DIC can be confirmed by the finding of several laboratory abnormalities, including the presence of thrombocytopenia, prolongation of the PT and aPTT, hypofibrinogenemia, elevated D-dimer, and the presence of schistocytes on peripheral smear. Not all these laboratory abnormalities need to be present to make the diagnosis of DIC, and no single laboratory test can confirm or exclude the diagnosis.\textsuperscript{54,56} The primary treatment of DIC is to treat the underlying inciting cause.\textsuperscript{54,55} Platelet transfusion is indicated only in those patients with active bleeding or in those who are at risk for significant bleeding. Such patients include those with platelet counts lower than 50 \times 10^9/L who need an invasive procedure or those with platelet counts lower than 10 to 20 \times 10^9/L.\textsuperscript{55} Cryoprecipitate can be used to correct severe hypofibrinogenemia (<50 mg/dL) in patients with active bleeding.\textsuperscript{54} No role exists for routine transfusion of cryoprecipitate in the absence of bleeding.

The use of low-dose heparin in patients with DIC has been suggested in an effort to reduce thrombin generation. This practice is controversial, however, because convincing data supporting its use are lacking.\textsuperscript{54,55}

LEADERSHIP QUALITIES

Plato pointed out that it is difficult to say what quality is but that one recognizes it when one sees it. The same can be said, to a large extent, about leadership. Everyone recognizes an outstanding leader, but, despite listing various characteristics, it remains difficult to say what exactly makes that individual a leader worthy of note.

What is a leader? What do leaders do? Are leaders really managers, or is it the other way around? Can one learn leadership? Are leaders necessary? How big must a group be before it needs a leader?

GROUP SIZE AND LEADERSHIP

Certainly, 2 people walking down a street do not need a leader, but observation tells us that 15 people walking down a street, as a group, do need leadership even for this simple task. The action as a group makes leadership necessary. Whenever one person acts in concert with another and is recognized to do so by others, then that group, as small as 2 individuals, needs a leader if for no other purpose than to communicate the needs and wants of the pair to the outside world. Obviously, leading a pair is easier than leading a group of 3, and so the complexity grows with each individual.

In large organizations (e.g., a university, a firm such as General Electric or Wal-Mart, the U.S. Navy), the leadership responsibility is divided at different levels. The chief executive officer (CEO) is expected to lead on matters of policy and general direction of the institution or corporation. As one travels down the chain of responsibility, the ratio of leadership to managerial skill changes.

MANAGER VERSUS LEADER

Managers direct processes, whereas leaders create change. Managers are given goals and are responsible for the tasks required to achieve that goal. The responsibility of a leader is to make the organization better by creating goals. The leader generates or adopts and then adapts the “better idea” to the needs of the organization.

“The reasonable man adapts himself to the world; the unreasonable one persists in trying to adapt the world to himself. Therefore, all progress depends on the unreasonable man.”

George Bernard Shaw
This process requires the leader to have a skill set for each of several roles:

**Visionary:** The ability to see that options exist.

**Decision maker:** The ability to choose among options. These options may be self-generated or given to the leader by others, but decisions need to be explicit and timely, neither too early (insufficient data, inadequately prepared staff) or late (problem requiring change is now too large, with a different set of options prevailing). Making decisions is hazardous, but leaders cannot be adverse to risk. Recognized leaders rarely revisit decisions and always look forward.

**Informant:** The ability to inform the members of the organization effectively of the nature of the change and the direction it will take and also inform related individuals outside the organization of how they will be affected.

**Tone setter:** Setting the tone (creating the atmosphere) that will allow the change to develop is actually more important than any policy that directs the change.

All these roles (visionary, decision maker, informant, tone setter) require unfailing attention to interpersonal skills for the simple reason that someone else, and various others at various levels, will, of necessity, be executing the change.

**CHARACTER**

The *primum non nocere* of interpersonal skills is character. Recognition by others that the leader is a person of character is the bedrock of the respect needed to take people to a goal.

“He listens, he is honest and he always takes the high road.”

Cheryl Kane, street nurse, Boston Health Care for the Homeless, about her boss, Robert Taube

Character and selfishness are mutually exclusive. The leader must see and be seen to understand that the needs of the organization override individual interests and that “doing the right thing” is always in the interests of the organization. This includes recognizing that the needs of the organization are best served when the appropriate needs of the individual are properly served in the context of the community that is the organization. Character requires commitment, focus, and a willingness to undertake and exercise responsibility, including accepting responsibility for failures. Failures will always occur as change proceeds. The absence of failures means that change is not happening.

“Most things you try will fail.”

Richard Pearle, MD, CEO Kaiser Permanente Northern California

“If you are not succeeding, you need to double your failure rate.”

Thomas Watson, founder IBM

Individuals of character rarely if ever complain, never gossip, and always follow through on what they said they would do. They are, and are seen to be, committed to making the organization and the individuals in it better. They hold themselves and others accountable while being loyal. Loyalty is a two-way street. The leader must be loyal to relevant external agents (the larger organization, the community, and its needs) while simultaneously acknowledging subordinates though recognition and by supporting them in time of personal need. Leaders are readily distinguishable from sycophants.

“Never complain, never explain.”

Anonymous

**STRATEGIC POSITIONING: OUT IN FRONT**

If the prime role of the leader is to take the organization to a different place, then he or she needs to be “out in front.” With a combination of knowledge of the organization as it currently exists and a clear vision of the goal of what it should look like in the future, both near and long term, the leader needs to pull the organization forward by using the respect that he or she enjoys as the rope.

The position out in front is not to place the leader on a pedestal, nor is it to isolate the leader in any way. In fact, the distance between the leader and the group is actually crucial. When it is too close, the leader is just another member of the group participating in the group think, whereas when it is too far, the leader is not seen to have any relationship with the group at all. Walking and talking too fast put more and more distance between the leader and the group and erode the necessary organic relationship between leader and followers.

For example, if the drum major is 10 yards ahead of the band, he is leading it; if he is 50 yards ahead, he has no useful relationship with it. His signals are difficult to see and difficult to interpret if they can be seen, and the musical cues are dropped, with results that one would expect. This principle is true irrespective of the nature of the organization.

“Take no credit; share no blame.”

Anonymous

**COMMUNICATION**

The person of character readily gains respect. This respect makes people willing to listen to what the individual has to say but, more important, makes them willing to talk to the leader because when integrity is recognized, trust exists. The individual telling his or her story is seeking, even demanding, attention and should receive it. That attention should be undivided because listening is the overarching virtue of a leader. The decision that follows is often viewed by the narrator as less important than the fact that the story was heard.

“Many a man would rather you heard his story than granted his request.”

Lord Chesterfield

There is much to be learned in listening. Buried beneath the words are essential truths about the individual and the job that he or she does, as well as the barriers that faced while doing it.

Discerning the nature and number of barriers to success at each level is a hallmark of a leader. It also implies the intention and action to remove those barriers and to allow individuals to succeed in their tasks.
Over and over, when individuals in large organizations are asked what could be improved in both their workplace and the organization as a whole, they reply “better communication.” By this, they imply the need to be listened to but also to be told “what is going on.” People left on the outside of the information stream feel powerless and neglected. Because a major purpose of any communication is to inform, the leader must be a successful informant. The message must be clear, so it must be simple and declarative. Avoidance of the passive voice enhances clarity. Jargon of any sort, whether medical, administrative, or managerial, should be avoided. The message must have a human touch to communicate not only the information but also sympathy with the recipient. To do this successfully in both written and oral forms takes practice and perhaps some coaching.

In the end, the whole purpose is to communicate the goal of the group and how any change promotes that goal. The goal itself must be a “good” something that makes both the group and the community better, and it must be easily recognized as such. Effective communication aids in this recognition. The “good” is a reflection of the leader’s beliefs, the underpinning of the leader’s character. The beliefs are then known and are seen to be the moral context in which goals and directives are enunciated. This sense of morality implies a sense of fairness and justice.

**FAIRNESS AND JUSTICE**

Fairness and justice imply the absence of a special relationship between a leader and other individuals. Experience tells us that these relationships prevent us from viewing the object of our friendship or affection objectively, thus suggesting unequal regard among all individuals of the organization. The wise and successful leader develops successful acquaintance- ship with members of his group but rarely friendship and never affection. This dispassionate approach is absolutely necessary to treating members of the group fairly and justly. Should affection develop, one of the individuals should leave the organization forthwith.

“Get your luvin’ at home.”

Peter Rosen

Also necessary for developing a sense of equity and fairness is the willingness to abide by the rules, whatever those rules may be. If the conclusion is that the rules are silly, counterproductive, or antiquated, then the successful leader will revise or remove them, but never ignore them.

**MANAGING LEADERSHIP**

Were one to possess and be able to exercise all the foregoing necessary virtues, one would be “the” natural leader, but such is only occasionally the case. Thus, one must have the ability to recognize one’s own weaknesses and “staff them.” This can be done by delegation. One may be excellent at decisional activities but a less than magnetic communicator. In that case, communication can, for some large part, be delegated, all the while taking precautions to ensure that the message is recognized as coming from the leader. The same holds for most activities, including fiscal, personnel management, and community affairs.

It is an unequivocal fact that some people possess leadership talent, whereas others do not. These other individuals may possess other talents that are useful for the organization, such as insight, salesmanship, or the ability to absorb and relate financial information. The successful organization places the individual with a particular talent needed in the position in which that talent is useful, and the individual, once placed, does the same all the way down through the organization. Having individuals in positions for which they have no talent is impairing both for the organization and for the individual, and if this position happens to be a leadership role, then the impairment reverberates widely. Having individuals succeed is a fundamental necessity to the success of the organization. Removing unsuccessful people from positions for which they have no talent is never a bad thing. Keeping them in the position in which they are not succeeding does a substantive disservice both to the organization and to themselves as it perpetuates dysfunction and delays their placement into positions in which they can succeed.

**LEARNING AND KNOWLEDGE**

Leaders must be knowledgeable. This requires being informed and trusting the informant. Thus, hiring trustworthy people is a key to success. This team of reliable informants helps the leader to “prepare relentlessly, to get the facts straight, to never assume anything.” Each episode of “doing the right thing and doing it correctly” sets an example of the standard expected of others. Just as a single adverse headline in a newspaper, truthful or not, can undo decades of reputation building, being mistaken even once on factual matters can serve to diminish credibility, a virtue on which leadership rests. This fact supports the notion that, as in everything else, successful leadership comes from talent supplemented by hard work. One can learn important elements of leadership, or at least improve on them.

Preeminent musicians practice several hours per day, as do star athletes. The skills of leadership are as amenable to improvement as any other skill. Presentation skills can be improved through education and practice. Focusing on individuals, for example, by learning and remembering names and personal facts of members of the team or work force, can alter the regard in which the leader is held, as can attendance at team social events. All these behaviors take initiative, time, and effort to learn and perform. Leadership is never a leisurely stroll in the park; attention can never lapse.

**EFFECTIVE LEADERSHIP**

Leadership is about promoting and managing change. Changing people is more challenging than changing material. The effective leader is one who regularly succeeds in driving change. The methods for this entail all the previously mentioned characteristics and character traits. Communication must be regular but not frequent, simple, consistent and persistent. It should antedate the effective date of the change by a period measured in months and should become more frequent as date nears. The communication should be seen to be personal, should explain the value of the change to the group, and should continue well into the implementation period, until the change is stabilized in the culture of the institution or
The record of accomplishment is the interface between the bedrock of character and clinical skill and the leadership position. Once a position is achieved, what successful leaders do in emergency medicine differs little from what successful leaders do in any other organization. The exception is that leaders in emergency medicine are more often expected to continue clinical activities, whereas in other organizations, especially large ones, no such expectation of “working on the shop floor” exists. On a local level, leaders seek to move the organization forward, including the physician group and hospital activities, both internal and external to the department, that affect the department. On a regional and national level, the principles remain the same; only the scale changes. Regional and national leaders in emergency medicine seek to initiate and manage change, be it through education, legislation, or offering new structures in national and state policy or new ways of thinking about processes. They set and move toward goals by seeking to align talent and job requirements, to make the workplace hospitable and just, thereby reducing costly employee turnover, and to inform peers, other members of the organization, the public, and politicians. They listen, act, take responsibility, and pause and reflect often.

**SUGGESTED READINGS**

“**Asking who the boss should be is like asking who should sing tenor in a quartet, it is the person who can sing tenor.**”

Henry Ford
Quality and Patient Safety in Emergency Medicine

Azita G. Hamedani, Jeremiah D. Schuur, Cherri D. Hobgood, and Elizabeth A. Mort

KEY POINTS

- The great variability in local and regional clinical practice patterns indicates that the U.S. population does not consistently receive high-quality health care. Problems with overuse, underuse, and misuse of health care resources have been documented.
- Two watershed Institute of Medicine reports brought the quality problems in health care to center stage. These reports championed that health care should be safe, effective, patient-centered, timely, efficient, and equitable.
- The greatest sources of quality problems in health care are not “bad apples” (i.e., incompetent providers), but rather “bad systems,” specifically systems that promote, or at least do not mitigate, predictable human errors.
- Medical errors and adverse events are caused by both active and latent failures, as well as factors (e.g., error-producing conditions or reliance on heuristics) that lead to cognitive errors (e.g., slips, lapses, premature closure). Diagnostic errors are a leading cause of patient safety issues in emergency medicine. High-reliability organizations are preoccupied with failures and serve as models for health care.
- Both public and private sectors have a strong movement away from purchasing health care services by volume and toward purchasing value (defined as health care value per dollar spent). Future reimbursement models will inevitably center on performance measurement and accountability, with a likely shift in level of financial risk borne from payer to provider.

HISTORY OF HEALTH CARE QUALITY

Efforts to assess quality in health care extend back to Dr. Ernest A. Codman, an early twentieth-century surgeon at Massachusetts General Hospital in Boston. Codman was the first to advocate for the tracking and public reporting of “end results” of surgical procedures and initiated the first morbidity and mortality conferences. Such public information would allow patients to choose among surgeons and surgeons to learn from better performers. Codman was clearly ahead of his time. The medical establishment resisted having their “results” measured and publicized, and Codman was accordingly ostracized by his peers. In 1913, however, the American College of Surgeons adopted Codman’s proposal of an “end result system of hospital standardization” and went on to develop the Minimum Standard for Hospitals. These efforts led to the formation of the forerunner of today’s Joint Commission (JC) in the 1950s. The JC’s accreditation process, local hospital quality reviews, professional boards, and other systems that developed allowed the medical profession and hospitals to judge the quality of their work and be held accountable only to themselves for most of the twentieth century.

The academic science of quality management in health care is credited to Dr. Avedis Donabedian’s efforts in the 1980s. Donabedian advocated for evaluating health care quality through assessment of structure (e.g., physical plant, personnel, policies and procedures), process (how things are done), and outcome (final results). His ideas were first adopted in public health and later spread to administration and management. Shortly thereafter, Dr. Donald Berwick, a Harvard Medical School (Boston) pediatrician, building on a systems approach to quality management, introduced the theory of continuous quality improvement into the medical literature. In his landmark New England Journal of Medicine article, Berwick remarked the that the “Theory of Bad Apples” relies on inspection to improve quality (i.e., find and remove the bad apples from the lot). In health care, those who subscribe to this theory seek outliers (deficient health care workers who need to be punished) and advocate a blame and shame culture through reprimand in settings such as morbidity and mortality conferences. The “Theory of Continuous Improvement,” however, focuses on the average worker, not the outlier, and on systems problems, rather than an individual’s failure.

Examples of bad systems abound in medicine. One example provided by Berwick involves the reported deaths resulting from an inadvertent mix-up of racemic epinephrine and vitamin E. Newborns in a nursery received the epinephrine instead of the vitamin in their nasogastric tubes. If presented as the mix-up of a benign medication for a potentially toxic one, it is viewed as appalling, and blaming individual negligent behavior is easy. Yet when one notes that the two bottles were nearly identical, one can understand why the system “is perfectly designed to kill babies by ensuring a specific—low
but inevitable—rate of mixups.” The Theory of Continuous Improvement suggests that quality can be improved by improving the knowledge, practices, and engagement of the average worker and improving the systems environment in which they work. The “immense, irresistible quantitative power derived from shifting the entire curve of production upward even slightly, as compared with a focus on trimming the tails” is what makes a systems focus so attractive (Fig. 208.1).

Although Berwick and others were publishing new studies critiquing health care’s approach to quality and safety throughout the 1980s and 1990s, not until the publication of two reports by the Institute of Medicine (IOM) did quality and safety capture the public’s attention: To Err is Human: Building a Safer Health System,5 in 1999, and Crossing the Quality Chasm: A New Health System for the 21st Century,6 in 2001.

To Err is Human focused the attention of the U.S. public on patient safety and medical errors in health care. The report’s most famous sound bite, that medical errors result in the deaths of two jumbo jetliners full of patients in U.S. hospitals each day, gained traction with lawmakers, employers, and patient advocacy groups. This estimate, that 44,000 to 98,000 deaths occur per year in the United States as a result of medical error, would make hospital-based errors the eighth leading cause of death in the United States, ahead of breast cancer, acquired immunodeficiency syndrome, and motor vehicle crashes. These statistics were derived from two large retrospective studies. In the Harvard Medical Practice Study,7 nurses and physicians reviewed more than 30,000 hospital records and found that adverse events occurred in 3.7% of hospitalizations. Of these adverse events, 13.6% were fatal, and 27.6% were caused by negligence. The Colorado-Utah study8 reviewed 15,000 hospital records and found that adverse events occurred in 2.9% of hospitalizations. Negligent adverse events accounted for 27.4% of total adverse events in Utah and for 32.6% of those in Colorado. Of these negligent adverse events, 8.8% were fatal. Extrapolation of results from these two studies provided the upper and lower limits for deaths associated with medical errors for the IOM report. In both studies, compared with other areas of the hospital, the emergency department (ED) had the highest proportion of adverse events resulting from negligence.

Crossing the Quality Chasm focused more broadly on redesign of the health care delivery system to improve the quality of care. The report begins by stating: “The American health care delivery system is in need of fundamental change. ... Between the health care we have and the care we could have lies not just a gap, but a chasm.” The report goes on to detail that this chasm exists for preventive, acute, and chronic care and reflects overuse (provision of services when potential for harm exceeds potential for benefit), underuse (failure to provide services when potential for harm exceeds potential for benefit), and misuse (provision of appropriate services, complicated by a preventable error, such that the patient does not receive full benefit). The report first defined six domains for classifying quality improvement for the health care system (Table 208.1). Together, the IOM reports solidified a key

</table>

COSTS IN HEALTH CARE

In 2009, the United States spent $2.5 trillion, or $8000 per person, on health care. Although we spend well over twice as much per capita on health care than any other industrialized country, we repeatedly fare poorly when compared with other systems on quality and outcomes. Half of the U.S. population admits to being very worried about paying for health care or health care insurance. One in four persons in the United States reports that his or her family has had problems paying for medical care during the past year. Close to half of States reports that his or her family has had problems paying for medical care costs, with reports of companies spending more on health care costs than on supplies for their main products. In Massachusetts, annual health care costs in school budgets outpaced state aid for schools and forced schools to make spending cuts in books and teacher training. The increased cost of U.S. health care threatens the ability of our society to pay for other needed and wanted services.

VARIABILITY IN HEALTH CARE

Although the number of errors coupled with increasing health care costs paints a negative picture, the variability of care is both more concerning and a source for optimism. Dr. John (Jack) E. Wennberg’s work in regional variability has illustrated the differences in cost, quality, and outcomes of U.S. health care since the 1970s. In 1973, Wennberg and Gittelsohn first identified the extreme degree of variability that exists in clinical practice by documenting that 70% of women in one Maine county had hysterectomies by the age of 70 years, as compared with 20% in a nearby county with similar demographics. Not surprisingly, the rate of hysterectomy was directly proportional to the physical proximity of a gynecologist. Similarly, residents of New Haven, Connecticut are twice as likely to undergo coronary artery bypass grafting (CABG), whereas patients in Boston are twice as likely to undergo carotid endarterectomy, even though both cities are the home of top-rated academic medical centers.

Dr. Wennberg’s work in regional variability led to the creation in the 1990s of the Dartmouth Atlas Project, which maps health care use and outcomes for every geographic region in the United States, and details care down to the referral region of each hospital. Atlas researchers, notably Dr. Elliott Fisher et al., have looked at the pattern of health care delivery and have found no clear association between the volume, intensity, or cost of care and patient outcomes. According to the Dartmouth Atlas Project, patients in areas of higher spending receive 60% more care, but the quality of care in those regions is no better, and at times worse, when key quality measures are compared. More widely reported in the lay press was the finding that Medicare spends twice the national average per enrollee in McAllen, Texas than it does any other part of the country, including other cities in Texas, without better-quality outcomes. The increased expense comes from more testing, more hospitalizations, more surgical procedures, and more home care. Variability in practice pattern, however, is not limited to overuse, but also includes underuse. McGlynn et al. found that, in aggregate, the U.S. population receives only 55% of recommended treatments, regardless of whether preventive, acute, or chronic care is examined.

The findings of the Dartmouth Atlas Project have frequently been cited as a rationale for health care reform law. The Project’s underlying methodology, however, has been scrutinized. Some investigators have questioned whether it appropriately adjusts for the costs of medical practice in different regions. Others have pointed out the limitations of focusing analysis on health care costs incurred by patients over the 2 years before their deaths and attributing these costs to the hospital most frequently visited. A study by Romley et al. reported an inverse relationship between hospital spending and inpatient mortality. Although great variability clearly exists in clinical practice, what is not clear is how to translate maps of geographic variation into health care policies that improve quality and contain costs.

One attempt at decreasing practice variability has been the rapid proliferation of clinical practice guidelines. Guidelines have been developed by physician specialty societies, hospitals, employers’ consortia, and government agencies (e.g., the Agency for Healthcare Research and Quality). The physician community, however, has been slow to adopt guidelines for several reasons. Some physicians disparage guidelines as “cookbook medicine,” whereas others point to the limited evidence on which these guidelines are built. Fear that deviation from guidelines may lead to more malpractice claims has also dampened enthusiasm for their use. Although clinical practice guidelines, order sets, and electronic decision support may not individually be the magic bullet for decreasing unwarranted clinical practice variability, all health care efforts should aim to be safe, effective, patient centered, timely, efficient, and equitable.

INSTITUTE OF MEDICINE AIM: PATIENT SAFETY

Echoing the ancient axiom of medicine, Primum non nocere, or “First, do no harm,” patients expect not to be harmed by the very care that is intended to help them. As such, patient safety is the most fundamental of the IOM’s six domains. Tables 208.2 and 208.3 provide the IOM’s Patient Safety and Adverse Event Nomenclature.

ACTIVE AND LATENT FAILURE TYPES

Failures in the ED fall into two main failure types: active and latent. Active failures are unsafe acts or omissions at the level of the front-line operator, such as the emergency physician (EP), nurse, or care provider, and the effects are felt almost immediately. This is sometimes called the sharp end of care. Latent failures are failures of the system that can lie dormant, or latent, for years. Despite, or perhaps because of, their obscurity, latent failures can cause multiple types of operator, or active, failures, yet go unnoticed to the casual observer; thus, they pose the greatest threat to safety in the complex ED system. Masked as the cause of incidents, these failures are powerful in joining with other factors to breach the system’s

concept—quality problems are generally not the result of bad apples but of bad systems. In fact, well-intentioned, hardworking people are routinely defeated by bad systems, regardless of training, competence, and vigilance.

Defences and coalesce in errors. In large part, latent failures are the result of decisions affecting daily ED operations, decisions often made by persons not directly involved in care delivery; for example, managers, designers, procedure writers, and drug manufacturers.

Active and latent failures are plentiful in the ED. An active failure occurs when a triage nurse accidentally measures a pediatric patient’s weight in pounds but writes down the weight in a chart box labeled kilograms instead. A similar error occurs when an EP orders antibiotics for a pediatric patient based on milligrams per kilograms (mg/kg) but uses weight in pounds instead. A latent failure exists when a patient with a pending pregnancy test undergoes computed tomography imaging before the positive result returns, or a patient with a pending creatinine test is given intravenous contrast before the abnormal results are acknowledged by the ordering provider.

REASON’S “SWISS CHEESE” MODEL

Described by James Reason in 1990,23 the “Swiss cheese” model of human error has four levels of human failure useful to evaluating a medical error (Fig. 208.2). The first level depicts active failures, which are the unsafe acts of the operator that ultimately led to the error. The next three levels depict latent failures (preconditions for unsafe acts, unsafe supervision, and organizational influence), which are underlying holes (or hazards) that allow errors to pass through to the sharp end. As with slices of Swiss cheese, when the levels of error are not aligned, an active failure can be caught before it causes harm—a near miss. With the right alignment, however, patients can be harmed by predictable human errors when systems are not appropriately designed to protect them.
COGNITIVE ERRORS

Cognitive errors fall into three distinct types: skill based, rule based, and knowledge based. Consider the act of driving a car or putting on your shoes. At some point, most of us acquired the requisite skills to accomplish these tasks quickly and efficiently without having to think about them. Skill-based cognitive performance refers to such acts. In the clinical setting, experienced clinicians approach the tasks of preparing a wound, tying a suture, or starting a central line in like fashion. Such clinical actions require little cognitive decision making. Skill-based errors are known as slips and lapses. Slips arise when actions fail to proceed as planned; for example, when a physician chooses an appropriate medication and writes 10 mg when the intention was to write 1 mg. Slips are errors in execution resulting from a failure of attention or perception often caused by interruptions or altered routines. In lay terms, slips are often equated with minor incidents. In the ED, patients can die as a result of slips. Lapses also result in failure to execute a plan, but whereas slips are observable, memory-based lapses are not. Pressing the wrong button on a defibrillator because you are interrupted and lose your train of activity is a slip; not being able to recall the correct energy to defibrillate ventricular stimulation is a lapse.

Any task departure from skills-based processing requires either a rules-based or a knowledge-based approach. Rules-based processing occurs when the clinician applies a known rule to make a decision. Rules, typically applied in the form “if X, then Y,” come from past experience, explicit instructions, or clinical guidelines. Traditional medical education is full of experienced-based rules, often termed clinical pearls. For example, the advice not to discharge a patient with abnormal vital signs is based on clinicians’ cumulative experience of reviewing adverse events after ED discharges. In contrast, the use of formalized clinical decision rules or guidelines (e.g., the Ottawa ankle rules to determine need for radiographs in ankle injuries) is another form of rule-based processing. Knowledge-based processing is when medical knowledge is applied and analytic processes are used to execute a plan of care. Errors of rule-based and knowledge-based cognition are known as mistakes. In rules-based errors, the wrong rule is selected, applied, or linked to the situation. Knowledge-based errors result when incomplete or incorrect knowledge is applied or flawed analytic processes are used, resulting in a poor plan of care. A mistake in medicine may involve selecting the wrong drug or treatment because of an incorrect diagnosis.

As clinicians gain experience, they engage to greater extent in skill-based and rule-based processing and to a lesser degree in knowledge-based processing. This shift in cognitive processing creates an interesting paradox with respect to the types of errors clinicians are most likely to commit. Although the rate of their knowledge-based errors is substantially reduced, highly trained individuals are more likely to experience skill-based errors, which are errors that arise from processes requiring the least amount of cognitive function.

EPs are at particular risk for cognitive errors related to the core tasks of the specialty of emergency medicine—the rapid evaluation of patients with undifferentiated complaints and the high-risk decisions that must be made with incomplete information.

HEURISTICS

Medical decision making in the ED is also characterized by a reliance on heuristics. Heuristics are shortcuts, rules of thumb, or any kind of abbreviated thinking that accomplishes quick and efficient decision making. Although they often serve EPs well, heuristics sometimes fail, thus leading to poor outcomes.

The four most commonly applied heuristics in emergency medicine are representativeness, availability, anchoring, and premature closure. The representativeness heuristic is applied when a clinician makes a subjective judgment of the similarity of a particular patient’s presentation to that of most patients who present with a particular condition. The more unrepresentative the patient’s presentation is, the greater is the chance that the diagnosis will be delayed or missed. Representativeness errors appear most often in settings of high diagnostic uncertainty, such as that typifying the ED, and they are more likely to be committed by clinicians with lower levels of experience. An example is the evaluation of a patient for thoracic aortic dissection, a relatively rare diagnosis. Although the classic symptom of a sudden onset of tearing thoracic chest pain that radiates to the back is not present in most cases, most physicians are less likely to consider this diagnosis without a representative presentation.

Another heuristic that can lead to errors in decision making is availability. Certain encounters are more prevalent in our memories, perhaps because they have occurred more recently, but more often because they are emotionally salient. When making diagnoses, human nature leads to an overreliance on encounters that are vivid and to place less importance on those least salient. For example, if a physician has a particularly vivid experience of missing an acute myocardial infarction (AMI) in a young person, the physician may become overcautious in managing similar patients with chest pain. Availability may similarly be increased by indirect experience: a recent discussion with a colleague, a case presentation at rounds, or an article reviewing a particular case. In contrast, availability is decreased by long intervals since encountering a particular disease, or never having previously seen it.

Anchoring results when physicians commit early to a diagnosis and give it undue weight when considering the available...
data. One way of avoiding anchoring is to ask “What else could this be?” and always to be disciplined in thinking about the differential diagnosis. The tendency to look for evidence that bolsters an original hypothesis is referred to as confirmation bias. Instead of ignoring conflicting data, EPs must look for disconfirming evidence that rejects the initial contention. If anchoring occurs early in a presentation and EPs operate under a strong confirmation bias, they are sure to miss diagnoses. For example, an older patient who presents with epigastric pain and a bulge in the abdomen could have either an incarcerated hernia or an AMI. A clinician who anchors on the diagnosis of incarcerated hernia can easily explain away tachycardia as the result of pain, and subtle electrocardiographic changes as nonspecific, rather than identifying them as the pattern of an early AMI.

Finally, premature closure occurs when a physician makes a quick diagnosis (often based on pattern recognition and not confirmed by appropriate testing), then stops collecting data, and fails to consider other possible diagnoses. Premature closure can occur in any case, but it is especially common when EPs take care of patients who seem to have an exacerbation of a known disorder. For example, a patient with a history of migraine is assumed to have another migraine, rather than an acute presentation of subarachnoid hemorrhage. Another example is a patient with chest pain and ST-segment elevation on the electrocardiogram who is assumed to be suffering from an acute coronary syndrome, rather than thoracic aortic dissection leading to coronary artery dissection.

Awareness of such cognitive biases is crucial, and simply knowing what they look like can help in overcoming them. Avoiding reflexive thinking and taking the time to think about how we think can help to minimize or avoid errors. Decision support tools, such as templated charts with potential diagnoses, or more sophisticated electronic tools that are queued by patient complaints and history, can help physicians overcome some of these biases.

ERROR-PRODUCING CONDITIONS IN THE EMERGENCY DEPARTMENT

The ED ranks among the top three hospital locations with the highest risk of error, along with the intensive care units and operating rooms. This finding is not surprising when one considers the combinations of error-producing conditions that exist in the typical ED. Many different providers (e.g., physicians, nurses, technicians) work closely together to care simultaneously for multiple patients of varying medical acuity who present with any imaginable chief complaint, from the most life-threatening to the most poorly defined, with whom these providers typically have no prior relationship. Providers are bombarded with multiple interruptions, and they struggle at times with understaffing and overcrowding while working through disruptive sleep cycles. As such, error-producing conditions in the ED include diagnostic uncertainty, low signal-to-noise ratio (i.e., the incidence of a serious condition or diagnosis [e.g., cauda equine syndrome] is low compared with more common and more benign diagnoses [e.g., musculoskeletal back pain]), high cognitive load, and poor feedback. Lack of continuity of care and unreliable and untimely feedback of patient diagnoses and outcomes make it difficult for EPs to refine their clinical skills continuously. A national survey of U.S. EDs documented commonly reported problems in four major areas: physical environment, staffing, inpatient coordination, and information coordination and consultation. The surveys suggest that the U.S. EDs have substantial room to reduce the latent conditions for errors.

HIGH-RELIABILITY ORGANIZATIONS

In the ED, we can learn from other industries (e.g., aviation, nuclear power) that have developed and incorporated systems allowing for early error corrections or prevention and leading them to function as high-reliability organizations. Such industries tightly couple the process of doing work with the process of learning to do it better. Operations are expressly designed to reveal problems as they occur. When problems arise, no matter how trivial, they are addressed quickly. High-reliability organizations share the following six traits:

Preoccupation with failure. These organizations are willing to examine any systems failure to identify causes. Even very small events are evaluated as opportunities to remove systems errors before they coalesce to create large, catastrophic system failures. The organizations have a strong culture of safety.

Reluctance to simplify interpretations. Such organizations seek materials and accurate appraisals of any failure. They do not simply blame individual workers and then consider the case closed.

Sensitivity to operations. These organizations methodologically approach each task with an eye toward improvement, by probing the systems factors that contributed to the failure.

Commitment to resilience. These organizations continually address a deficit until resolution occurs.

Understanding of expertise. These organizations defer decisions to the person who has the requisite knowledge, rather than the requisite rank.

Clarity in mission and vision. A common view of the world allows team members to communicate accurately.

Understanding the importance of a culture of safety in the strive for high quality, Johns Hopkins Hospital (Baltimore) researchers implemented a comprehensive, unit-based safety program (CUSPS) at almost 150 individual units in the hospital. This program ultimately led to the establishment of an organization-wide culture of safety at the hospital. Although in the past, organizations focused many resources on building a culture of safety, patient safety leaders have shifted to advocating for a just culture, one that balances safety with accountability. Whereas a culture of safety allows evaluation of suboptimal medical outcomes without fear of punitive action toward individuals, a culture of accountability also encourages providers to do the right thing, especially when doing the right thing is easy. A notable example is facilitating hand hygiene through provision of soap dispensers in key locations while holding providers accountable for their individual behavior through direct observation and feedback.

INSTITUTE OF MEDICINE AIM: TIMELINESS

Timeliness is a core mission of the specialty of emergency medicine. In a little more than one decade, ED visits have
grown by nearly 25%, whereas at least 10% of EDs have closed nationally. This situation has caused many EDs to experience increased waiting room times, length of stay, and boarding of inpatients in the ED. In fact, up to 25% of patients are not seen by an EP within acuity-based recommended times, and patients with AMI have experienced a 150% increase in wait times over this period. Deaths in the waiting room reported in the lay press serve as a stark reminder of the consequences of systems failures on individual patients.

Although one goal of health care reform is to decrease ED visits, to date, large-scale health systems reforms have not been able to do this. In fact, given aging demographics (older patients have a higher ED use rate) and patient preferences (for rapid acute care at the time of their choosing), current crowding trends are likely to continue. Furthermore, if efforts at health care reform lead to an increased number of insured patients, Massachusetts’ experience of requiring individual to obtain health insurance (the individual mandate) suggests that more, rather than fewer, ED visits can be expected in the near term.

A growing body of evidence links prolonged ED length of stay, ED crowding, and boarding of inpatients in the ED to lower quality care and worse patient outcomes. ED crowding has been associated with worse-quality care for patients with AMI, acute coronary syndromes, and hip fractures. For example, cardiac patients boarded in the ED for longer than 8 hours are less likely to receive guideline-recommended therapies and are more likely to have recurrent MIs. Given prolonged wait times to evaluation in the ED, one study evaluated the safety of managing potential cardiac patients in the ED waiting room. Although approaches such as this, to improve safety in the crowded ED, are reasonable short-term solutions, they do not address the primary latent failure of ED crowding, which is the inability to evaluate and treat patients in the appropriate location in a timely fashion.

Given the challenge of addressing quality and safety issues in a crowded ED, many departments are redesigning their operations and patient flow models to improve the timelines of care. Most notably, newer models of care have been developed to replace the traditional model of ED care that was serial (e.g., patient triage, then nursing evaluation, then physician evaluation, then laboratory or diagnostic testing, then decision on final disposition) and uniform (regardless of patient’s clinical needs). Newer models of care have several common features: optimizing front-end operations, developing multiple pathways through the ED that attempt to match a patient’s acuity and resource needs, eliminating duplicate evaluations, maximizing the use of limited ED beds, and facilitating rapid discharge of patients. One example is vertical patient flow, a model in which a cohort of patients, rapidly identified on arrival to the ED, is evaluated, managed, and either admitted or discharged in advance (or in lieu) of occupying a traditional ED bed. These patients (often a subset of Emergency Severity Index [ESI] 3 patients) require greater medical decision making and more resources than do fast-track patients, but they do not require a room and a stretcher for evaluation. Because these patients do not need to be disrobed in a private room for most of their ED visit, they can sit in recliners in an internal waiting room for most of their ED visit.

The IOM report identified patient-centered care as a core element of quality. Although many physicians equate patient-centeredness with patient satisfaction, satisfaction is only one component of patient-centeredness. Patient-centered care respects individual patients by addressing the values, ethnicity, social situation, and information needs of each patient. Although patient satisfaction surveys have been used for a long time in emergency medicine, only more recently have EPs begun to implement changes that strive to make emergency care more inclusive and responsive to patients’ values, needs, and wishes. Two notable examples are the move to include families in resuscitations and the use of structured decision aids to guide joint medical decision making. Historically, family members were kept out of ED resuscitation rooms when their loved one was undergoing advanced resuscitation (e.g., cardiopulmonary resuscitation). Studies show that family members benefit from their involvement at the end of the patient’s life because the resuscitation, instead of being traumatic, often helps bring closure to a tragic event. A second example is using structured decision aids to engage patients in complex diagnostic decisions, such as whether to conduct cardiac risk stratification in the ED, in the hospital, or in the outpatient environment. When presented with well-designed decision aids, patients are both less likely to request more resource-intensive testing and more likely to be satisfied with their care.

According to the IOM, effective care should be based on best evidence, thus avoiding inappropriate underuse or overuse. The literature supports the care of some common patient presentations (e.g., syncope, sepsis). Much room for improvement remains, however, because much of emergency practice is without a strong basis in the literature. In this relatively new specialty that deals with a diverse patient population under challenging clinical conditions, conducting methodologically rigorous clinical research has been difficult. Much of the evidence that has been cited to justify emergency practice is from other populations, clinical venues, and focus on nonemergency outcomes. This situation is illustrated by the paucity of level I recommendations in the American College of Emergency Physicians Clinical Policies. As in other areas in which clinical practice has been studied, tremendous provider-to-provider variability exists in emergency medicine. The hope is that minimizing this variability by developing evidence-based guidelines will allow EPs to provide effective care more reliably.
Unfortunately, ED care is widely viewed by the medical community as inefficient. This view is often based on comparisons of charges and costs for ED visits and primary care physician visits for simple presentations, such as sore throat or ear infections. The true marginal cost of such patient visits in the ED is open to debate, however, given the high fixed expenses associated with operating a clinical environment 24 hours a day, 365 days a year. More problematic is the view that all emergency visits are avoidable and examples of failures of the health care delivery system. Clearly appropriate ED visits for patients range from heart attacks and strokes to stab wounds and motor vehicle accidents.

EPs can respond to the push for increased efficiency in the health care system by looking for ways to deliver their care with less waste. For example, efficiency measures focused on appropriateness of imaging studies are likely to be defined. By reducing inappropriate and unnecessary testing, EPs can improve the efficiency of emergency care without reducing quality or access.

The IOM defined equitable care as care that does not vary in quality based on personal characteristics (e.g., race, gender, geographic location, socioeconomic status). Although most EPs pride themselves on providing equal care to all, regardless of ability to pay and personal background, studies have documented racial disparities in emergency care. Significant room exists for future research on equality of emergency care because it has received little research attention.

**SPECIAL FOCUS: CARE COORDINATION**

Appropriate care coordination around transitions of care is a topic that cuts across multiple domains of quality. The totality of care cannot be timely, efficient, and patient centered if it is poorly coordinated during the many hand-offs that occur in health care. For example, almost 20% of Medicare beneficiaries are rehospitalized within 30 days of hospital discharge, and half of these patients did not have an intervening primary care visit.

Care coordination is especially important for “hot spotters,” patients who are extreme outliers in health care use and cost. Although 10% of patients account for two thirds of all U.S. health care costs, these extreme outliers (top 1%) account for a significant fraction of costs by themselves. Intensive outpatient care for complex high-needs patients can significantly reduce health care costs. So far, these efforts have viewed ED visits as systems failures and have not engaged emergency caregivers, but such programs will likely be more successful if they integrate coordination of care plans between the outpatient providers and the local ED providers.

More directly affecting ED care are the hand-offs between physicians at change of shift or on patient admission. Communication errors are the root cause of most safety events that occur in the ED. Many quality lapses occur when critical information is lost in such transitions. Many barriers to effective communication exist, including the need to balance conciseness with completeness, the lack of a standardized approach, and ambiguous time stamp for when transition of care occurs. Nonetheless, Cheung et al. provided with strategies to improve hand-offs, including reducing the number of unnecessary hand-offs, limiting interruptions and distractions, communicating outstanding tasks and anticipated changes along with a clear care plan, encouraging questioning of assessment, and signaling a clear moment in transition of care.

**SPECIAL FOCUS: FROM “NEVER EVENTS” TO “SERIOUS REPORTABLE EVENTS”**

The most high-profile patient safety errors have been those that were serious and preventable. This is not surprising because explaining to a patient or patient’s family how a system allows such events to occur again and again is difficult. For example, at one hospital in Rhode Island, neurosurgeons operated on the wrong side of a patient’s brain three times over the course of 3 years, and an additional two other wrong-site surgical procedures occurred in this time. Such errors were initially labeled “never events”—events that should never occur. However, as the number of preventable events (e.g., hospital-acquired infections) grew, maintaining the paradigm of never events became difficult. Instead, the focus was changed from events that should never occur to ones that should not occur.

As such, in 2002, in an effort to develop a single standard list of serious medical errors requiring reporting, the National Quality Forum convened a multidisciplinary group that developed a consensus list of Serious Reportable Events in Healthcare (SREs). The goal of defining SREs was to guarantee that serious patient safety events would undergo systematic review to determine causes and contributing factors and that the findings would be used to improve care and avoid future events. Given public reporting requirements and potential nonpayment, SREs represent an important hospital patient safety priority.

**FINANCIAL STRATEGIES TO IMPROVE HEALTH CARE QUALITY AND VALUE**

**CENTER FOR MEDICARE AND MEDICAID SERVICES**

As the country’s largest insurer and purchaser of health care services, the Centers for Medicare and Medicaid Services (CMS) is very interested in making sure its health care dollars
are being well spent. Toward the aim of increased transparency and accountability, CMS launched a public reporting effort in 2004. Initially, participation in Hospital Compare (www.hospitalcompare.hhs.gov) was voluntary, and only quality measures related to pneumonia, AMI, and congestive heart failure were reported. Since then, the number of measures reported on this website has dramatically increased, and it includes risk-adjusted death and readmission rates, as well as patient satisfaction.

In 2007, the CMS rolled out a Physician Quality Reporting Initiative (PQRI), which has since been renamed the Physician Quality Reporting System (PQRS). Initially, physician groups received a 2% bonus for participating in the program. By 2014, that amount will decrease to 0.5%. Starting in 2016, physicians who do not participate in PQRS will see a 2% reduction in their Medicare payments. EPs have notably had one of the highest participation rates among all the specialties.

In January 2011, the CMS launched a Physician Compare website. Although it started with simple provider-specific information (e.g., whether a physician accepts Medicare and uses electronic prescribing), by 2015 it is expected to have public reports of physician-specific quality measures, including patient satisfaction. Developing physician profiles is replete with challenges. One of the most important unintended consequences of physician profiling is risk aversion (physician’s avoiding complex or high-risk patients), which inevitably leads to decreased health care access for minorities and economically disadvantaged populations. Most problems have been physician cost profiling because current methods misclassify physician ranking one fourth of the time. The reliability of these profiling schemes therefore is paramount.

The Affordable Care Act established an Innovation Center within the CMS to test innovative payment and health care delivery models, aimed at reducing health care expenditures and improving quality. For example, the Innovation Center will likely link payment to hospitals to their ability to reduce hospital-acquired infections and readmissions. The effectiveness of such financial incentive programs has been drawn into question. Looking at data from the United Kingdom’s Quality and Outcomes Framework, researchers did not find any improvement in outcome measures for patients treated before or after the introduction of the incentive program.66

**FUTURE REIMBURSEMENT MODELS**

In both public and private sectors, a strong movement is leading away from purchasing health care services by volume and toward purchasing value (defined as health care value per dollar spent). Reimbursement models are evolving to motivate providers to be more cost and quality conscious. Since 2000, several schemes have emerged that have been called pay-for-performance (P4P) programs. Many of these programs were simply fee-for-service models, with either a bonus or withhold based on achieving certain performance thresholds.

A newer, emerging reimbursement model is bundled payment, in which hospitals and providers share in the accountability for delivering value. Geisinger Health System’s ProvenCare program defined and implemented best practices for patients undergoing CABG and then offered risk-based pricing to insurers. Specifically, preoperative, inpatient, and postoperative care within 90 days was packaged into a fixed price and touted in the lay press as a “CABG warranty.” The success of this program in improving care and reducing costs brought the concept of bundled payments to the center stage of health care reform.

Global or capitated payment is also reemerging as a viable way to reimburse for care. Blue Cross/Blue Shield of Massachusetts reported that its global payment system improved patient care during its first year, including decreasing avoidable ED visits by 25% through one of its contracts. Under an alternative quality contract, physicians are provided a monthly per-patient budget, as well as bonuses for improving care. Future reimbursement models will inevitably center on performance measurement and accountability, with a likely shift in level of financial risk borne from payer to provider (Fig. 208.4).

To be fiscally viable within potential future reimbursements models, health care providers are being encouraged to organize themselves into accountable care organizations (ACOs). ACOs are meant to encompass various provider arrangements (e.g., integrated delivery systems, multispecialty group practices, physician-hospital organizations, independent practice associations) that lead involved parties (e.g., physician group and hospital) to be jointly accountable for improving patient care and reducing spending. Unlike an HMO, this needs to be accomplished within the context of patients’ choice to visit providers internal or external to the ACO for which their care is attributed. Ideally, ACOs will be able to bend the cost curve of increasing health care expenditures. Many different prototypes have been reported in the lay and medical literature. Certification of ACOs for participation in the Affordable Care Act’s Shared Savings Program for Medicare still must occur. A fine balance will need to be reached because a liberal policy may lead to provider mergers and market dominance that have driven up costs in the past.

**MEASURE DEVELOPMENT**

Future reimbursement models will depend on development of methodologically sound quality measures, and particularly on measures of outcomes of care. The most easily accessible outcome measures (e.g., mortality rate, readmission rates) are important but nonspecific measures of quality.

To date, numerous organizations have developed quality of care measures ranging from academic researchers, to individual hospitals and health systems, to federal agencies and their contractors. Although virtually anyone can develop a potential measure, several organizations have taken the lead in reviewing and endorsing measures of quality of care.

The American Medical Association’s Physician Consortium for Performance Improvement is composed of all the
medical specialty societies and leads projects to develop measures for individual specialties and for conditions that cross specialties (e.g., stroke). Similarly, the National Center for Quality Assurance has taken the lead in developing measures of care for insurance plans and health care systems. The National Quality Forum (NQF) is a public-private venture whose mission is to improve health care by endorsing consensus-based national standards for measurement and public reporting of health care quality data. Payers and government agencies, such as CMS, rely on the NQF to endorse valid performance measures.

Emergency medicine faces a unique challenge in developing and commenting on potential quality measures. Because EPs care for patients with all types of conditions, many specialties and condition-specific quality measure sets could measure and judge emergency care. As such, the American College of Emergency Physicians and the Society for Academic Emergency Medicine have lobbied to have EPs included in quality measure development panels that affect emergency medicine.

Without representation, poorly framed, yet nationally endorsed, quality measures may negatively affect emergency care. For example, the initial measure set for community-acquired pneumonia was developed using low-quality evidence from cross-sectional Medicare studies. EPs contended that these measures had many unintended consequences, including the administration of inappropriate antibiotics and excessive use of blood cultures. As more research was published showing that these measures were not linked to improved patient outcomes, the CMS revised the measures (Box 208.1).

Despite an increased focus on transparency and systems improvement (Box 208.2), physicians and hospitals continue to underreport their errors and quality lapses. Too often, providers react to medical errors with shame, fear, and secrecy. To most physicians, the admission of wrongdoing has the dual effect of causing humiliation in front of patients and peers and introducing fear of lawsuits into everyday life. Ofri reported, “No doctor will easily confess to error when a core sense of self is at risk. … Unless we can defuse the shame and loss of self that accompany admitting medical errors, there will always be that taut inner core of resistance.”

### BOX 208.1 Blood Cultures for Community-Acquired Pneumonia

This measure serves as an example of a measure with a poor scientific basis and little regard for implementation feasibility. These guidelines were developed and approved without adequate input from the emergency medicine community. Despite feedback and modification, the current measures are not evidence based, they require laborious chart review, and performance is more easily improved by modifying documentation than by improving processes of care.

- **1998 and 2000**: Clinical guidelines for CAP published by specialty societies recommend routine blood cultures for patients admitted with CAP (e.g., the Infectious Disease Society of America).
- **2000**: A technical panel charged to develop CAP quality measures from the Oklahoma Foundation for Medical Quality reviews the guidelines and recommends blood cultures in pneumonia as a CAP measure to CMS and the Joint Commission.
- **2000**: Once approved by CMS and the Joint Commission, the measures are then submitted and endorsed by the National Quality Forum.
- **2002**: The measures are adopted as National Hospital Quality Measures, and results are reported on the Hospital Compare website.
- **2004 and 2006**: Because of feedback from emergency physicians, the measures were revised several times to limit the eligible population. The first revision limited the applicable patient population to those admitted to an ICU within the first 24 hours of their stay. The second revision further refined the eligible population as the subset of patients with CAP who have cultures drawn in the ED.
- **2011**: Current CAP measures are as follows:
  - The proportion of patients admitted to the ICU within 24 hours of hospital arrival because of pneumonia who have blood cultures obtained within 24 hours of arrival
  - The proportion of patients who have blood culture drawn in the ED who have the culture drawn before antibiotic administration

CAP: Community-acquired pneumonia; CMS, Centers for Medicare and Medicaid Services; ED, emergency department; ICU, intensive care unit.
In most emergency medicine residency programs, the morbidity and mortality conference is the most widely used error-based teaching conference. The culture of this conference helps shape physicians’ view of medical errors. One step in the right direction is for senior EPs to share their own mistakes with the next generation of physicians in an open and safe manner and to encourage reporting of errors, especially when appropriate peer-review protected systems are in place. Another cultural change is for EDs and hospitals to adopt policies encouraging rapid and open admissions of error to patients. Although individual physicians can adopt this strategy, it may be most effective if adopted by an institution and supported with changes in the way patients are compensated for medical errors. In 2001, the University of Michigan adopted a program of full disclosure of medical errors with offers of compensation. This approach both decreased the number of lawsuits and the time to resolution, without increasing the overall amount spent on medical malpractice.66

**REMAINING CHALLENGES**

Although more than a decade has passed since the IOM reports were published, studies still show that nearly 20% of patients continue to be harmed by their care.67 In addition, one in seven Medicare beneficiaries will experience adverse events while hospitalized, and SREs (e.g., wrong site surgery) continue to occur.68 Furthermore, physician involvement in quality improvement activities varies considerably and will become mandatory only as each specialty board incorporates quality improvement into its maintenance of certification programs.69 The American Board of Emergency Medicine requires a “patient care practice improvement activity” for those diplomates recertifying in 2013 and beyond.

No one can predict today what our health care system will look like in 3, 5, or 10 years. Current visions of bundled payment systems and ACOs are based more on theory than on experience. What one can be certain of is that pressure to address the rising costs of health care and the variable and often inadequate quality and safety of health care will continue. These pressures will lead to dramatic changes in the way physicians and hospitals are organized. The ED of 2020 may contain many more or many fewer patients, depending on how the system evolves. Yet EPs are uniquely qualified to understand quality and safety throughout health care systems and to mobilize multidisciplinary teams to address these challenges. EP engagement in improving care from the ED to the greater health care delivery system is needed now more than ever.

---

**BOX 208.2 Quality Improvement Toolkit**

**Investigate**
- **RCA (root-cause analysis):** This is an attempt to learn the underlying systems cause of problems (e.g., equipment, staffing, policies and procedures, information systems), frequently by asking “why” five times until the root cause is identified; it is facilitated by use of a fishbone diagram.
- **FMEA (failure modes and effects analysis):** This is a systematic, proactive method for evaluating a process to identify where and how it may fail and to assess the relative impact of different failures to identify the parts of the process that are most in need of change.

**Mitigate**
- **Standardization:** Consistency minimizes errors caused by varied processes (e.g., using the same tube thoracostomy set throughout the hospital).
- **Simplification:** The more steps a process has, the more likely it will be that a given process will go wrong (e.g., different admitting procedures for different services within the same hospital).
- **Checklist:** This was made famous by Pronovost’s Keystone Initiative, which showed that a simple checklist for central venous catheter placement in the ICU could substantially decrease the infection rate.
- **Forcing function:** Systems designs make it difficult to do the wrong thing (e.g., gas connectors on anesthesia machines are designed so that oxygen and nitrous oxide tanks can be attached only to proper ports, thus eliminating the potential of a fatal mix-up) or make it easy to do the right thing (e.g., opt-out provisions for deep venous thrombosis prophylaxis as part of inpatient order sets decrease the rate of subsequent pulmonary embolus).

**Improve**
- **PDCA (plan, do, check, act):** Identify a problem, plan a solution, execute the plan on a small scale, measure performance, check to see whether the plan resulted in the desired outcome, make changes to improve the plan, and/or execute the plan on a larger scale. In terms of improving the daily practice of medicine, PDCA cycles are more useful than formal studies (e.g., randomized trials) and erratic trial and error approaches.
- **LEAN:** with the use of value stream maps, lean thinking identifies value-added and non-value-added steps in every process, with the goal of driving out waste so that all work adds value and serves the patient’s needs.

---

**TIPS AND TRICKS**

**Tell the Truth: Disclosure of Medical Errors**

Physicians may not be providing the information patients want about errors. Although physicians disclose the adverse event, they often avoid stating that an error occurred, why the error happened, or how recurrences could be prevented. Physicians should disclose the following minimal information about harmful errors, even if not requested by the patient:
- An explicit statement that an error occurred
- A basic description of the error, why the error happened, and how recurrences will be prevented
- Emotional support, including an apology

Conflict in medicine is relatively easy to understand if one considers physician attributes, such as a tendency toward perfectionism and delayed social development. These characteristics are highly adaptive to doctoring, reinforced by values such as religious, ethical, financial, or those involving patient care. Values (beliefs) are fundamental to conflict. Core values, such as religious, ethical, financial, or those involving patient care are difficult to change and therefore generally assume a large role in conflict. Value differences among people or groups (e.g., health care professionals and physicians with different training) may result in repeated conflicts. The expectations that EPs have of hospital and emergency department (ED) staff regarding work ethic or efficiency, for example, often result in conflict (perceived or real). Under these circumstances, people feel as if their integrity is being questioned, and this is one reason that value-based conflicts are extremely difficult to resolve.

Conflict is inevitable. Opportunities for conflict in emergency medicine (EM) are numerous because individuals with different backgrounds and divergent agendas interact over important concerns (e.g., patient care or resource use). By nature, these interactions take place under time constraints, which often exacerbate conflict. Many interactions between emergency physicians (EPs) and patients, family members, staff members, or consultants occur with limited or no previous working relationship or when prior interactions have been problematic. As such, involved parties may be unable to reflect on prior successful interactions, an approach that often decreases the likelihood of intense exchange.

Controversy exists about the value of conflict. Many believe that, at its best, conflict is disruptive. Most agree that, at its worst, conflict is destructive to team harmony and patient outcomes. However, conflict also serves as a creative force, providing both initiative and incentive to solve problems.

This chapter describes conflict in general, identifies contributing factors, and offers several examples specific to EM. The importance of effective communication in conflict resolution is presented, as well as its role in de-escalating, limiting, and preventing conflict. This chapter offers strategies to facilitate successful conflict resolution. Conflict resolution ultimately benefits patients, staff, and EPs by optimizing patient care, decreasing patient morbidity, improving patient safety, and maximizing an individual’s or health care team’s overall satisfaction.

Communication, in the form of language and interaction, and power, in terms of how conflict is managed (or mismanaged), are tremendously important in the dynamics of groups. EM is very much about group dynamics because physicians, nurses, and other staff members must consistently demonstrate successful teamwork to offer patients the best possible outcomes. Louise B. Andrew, MD, JD, stated “… conflict is often the result of miscommunication, and may be ‘fueled’ by ineffective communication.”

Three important sources of conflict have been identified: resources, psychological needs of individuals or groups, and values. Resource-based conflicts relate to limited resources, common in EM. Psychological needs include power, control, self-esteem, and acceptance. These needs often exist under the conflict’s surface and can be difficult to identify or address. Values (beliefs) are fundamental to conflict. Core values, such as religious, ethical, financial, or those involving patient care are difficult to change and therefore generally assume a large role in conflict. Value differences among people or groups (e.g., health care professionals and physicians with different training) may result in repeated conflicts. Conflict in medicine is relatively easy to understand if one considers physician attributes, such as a tendency toward perfectionism and delayed social development. These characteristics are highly adaptive to doctoring, reinforced...
by training, and rewarded by society. These traits may be maladaptive when it comes to communicating and interacting with nonphysicians, however, with resulting conflict and poor conflict management.

The ED environment is particularly predisposed to conflict for many reasons. Differences in professional opinion and value systems among staff members and patients are contributing factors. EPs must interact with individuals in all areas of health care, at any time of day or night, and during periods of great stress. EPs are unlikely to know everyone on every service with whom they must interact. This challenges EPs because they are not familiar with each medical staff members’ idiosyncrasies, preferred practice pattern, or communication style. These interactions create even greater difficulties for new EPs, who lack histories of favorable reputations or successful relations with hospital staff, thus significantly increasing the likelihood of conflict.

**EXAMPLES OF CONFLICT**

Conflict in EM results from a mismatch of expectations among patients, family members, providers, or consultants, as well as among nurses, ED staff, or ancillary staff outside the ED. Patients and family members may have unrealistic expectations about their ED experience, not to mention the pain or fear that brought them to the ED. Nurses may have unrealistic expectations of physicians and generally have widely differing backgrounds. Although gender representation of EPs has become more equal, older EPs tend to be male, whereas nurses are predominantly female. Misunderstandings and communication problems exist in the workplace between genders and age groups. Additionally, each time a consultant is contacted, his or her practice, social life, or sleep is disrupted. This added workload alone may ignite conflict.

Numerous additional factors further explain the high likelihood of conflict in EM. Diversity in training, experience, and perspective often result in differences of opinion between EPs and colleagues from other areas of medicine, including nursing. For example, conflict arises simply because EPs do not want to send someone home who should not go home, whereas hospital-based physicians or specialists may prefer not to admit (or may be pressured not to) patients who do not require admission. These two opposing “forces” create conflict.

The responsibility of patient advocacy assumed by EPs and ED staff often creates conflict because it may not coincide with the interests of the patient or family members. If a patient’s decision-making capacity is impaired or their legal advocate is not present, EPs have the duty to act in the best interest of the patient, state, or society, regardless of the patient’s wishes. One common challenge occurs when a patient with a history of substance abuse and chemical dependency demands narcotics for “pain.” An EP’s refusal to prescribe narcotics is certain to create conflict. Conflict also occurs when a patient or family member desires admission to the hospital without medical justification, a test that is not indicated or available (or may be harmful), or consultation with a specialist that is medically unnecessary or inappropriate at that time. Other times, an EP may believe that it is in the patient’s best interest to be admitted to an inpatient medical service even if hospitalization may not influence the ultimate outcome, and this creates conflict with the admitting service. Conflict may also develop between two services over which service will admit a patient. The EP must mediate this dispute while keeping the patient’s needs and interests at the discussion’s forefront.

Perhaps the area most likely to create conflict is ineffective or incomplete communication between or among two or more parties. Given cultural and language differences among patients, families, nurses, staff, and consultants, communication challenges prime the ED for conflict. Frustration, unmet expectations, time constraints, and limitations on staffing, equipment, space, and privacy may be overwhelming if communication is suboptimal or barriers to effective communication exist.

Because the specialty of EM is so complex and has tremendous liability associated with its practice environment, many areas of potential conflict have been addressed at federal, state, and local levels. Hospital policies and bylaws have established guidelines addressing these issues, in an attempt to prevent conflict before it occurs. Despite these policies, conflict still occurs. EM organizations are addressing these and other areas of potential conflict, based on the needs of emergency patients and professionals. As health policy and the specialty of EM evolve, new challenges will be identified, with more issues requiring resolution (Box 209.1).

**BOX 209.1 Areas of Conflict Related to Emergency Medicine**

1. Differences in education, background, values, belief systems, and interpersonal styles of communication between EPs and others
2. Commitment to patient satisfaction
3. Final patient disposition (and who determines this)
4. Timing of follow-up care and outpatient tests for released patients
5. Telephone conversations required for patient care issues
6. Lack of professional respect from primary physicians or consultants
7. Dual advocacy expected by others for the EP
8. Teaching hospitals with house staff who may lack communication and conflict resolution skills, have less commitment to the hospital, patients, or ED staff because of temporary scheduling at that hospital or ED, and sense a lack of input, ownership, and control over patients’ (or their own) lives
9. Patient transfers to or from the ED
10. Time limitations and urgency
11. Practice variability, including patient hand-offs
12. High patient acuity and volume
13. Space issues and patient privacy
14. Federal or hospital reporting mandates
15. EM practice, such as caring for multiple patients with limited information, with risk of great morbidity and mortality
16. Threat of litigation related to high stakes, clinical challenges, and patient’s lack of previous personal relationship with EPs

*ED, Emergency department; EM, emergency medicine; EP, emergency physician.*
Many challenging situations that result from the nature of EM practice are less likely to create conflict than in previous decades because hospital administrators seem more willing to collaborate with ED leadership to prevent conflict before it occurs. Many EM leaders are sharpening administrative skills to allow them greater success when exchanging ideas with hospital leaders. Opportunities for communication, education, and problem solving in areas prone to conflict, especially during “business hours,” are in the best interest of patients and the entire medical staff.

**IMPORTANCE OF COMMUNICATION**

Effective communication is extremely important to the process of conflict resolution. For effective communication to occur, mutual respect and concern must exist between parties. This includes respect for an individual’s professional and personal choices. Many physicians have difficulty interacting with individuals who do not share similar values, such as work ethic, practice style, or lifestyle.

Communication is difficult for various reasons, especially because many physicians are poor listeners. Physicians interrupt patients early and often; these patterns are likely present during communication with colleagues and team members, especially during stressful situations. In the ED, time constraints make communication challenging, as does the fact that most communication occurs in a public area. Communication often is done by telephone or electronically, which eliminates visual cues. Furthermore, individuals may have unique or differing agendas that make it even more difficult to communicate efficiently, let alone effectively. Past interactions affect future communications. Previous negative interactions are far more likely to be remembered than are positive interactions. The personalities of different specialists often clash, thus contributing to the likelihood of conflict.

The role of stress on physician communication must not be overlooked. Besides patient care stressors, contacting physicians about patient care issues, particularly at night, is stressful for EPs. It is especially difficult for EPs to contact physicians with hospital leadership roles, with reputations of demeaning behavior, or in senior positions that may affect partnership opportunities or future employment. These situations may directly or indirectly result in less than optimal patient care when an EP’s desire to avoid conflict takes priority. Fortunately, instruction in communication and conflict resolution is required not only in EM training programs but also by medical schools and other residency training programs.

**COSTS OF CONFLICT**

What are the costs associated with conflict in EM? Staff morale is likely to be low in EDs with high levels of conflict. Staff turnover and dissatisfaction with the work environment are likely to be high. Management will probably need to address an increasing number of complaints about the ED from it and other areas of the hospital, and that takes up valuable administrative time. Conflict interferes with patient satisfaction, throughput, quality of care, and patient safety. Pride in the ED may decline, thus further reducing morale and creating a potentially debilitating negative spiral.

Conflict (and poor conflict resolution) increases the likelihood that the ED is an unpleasant place to work; this increases stress and decreases everyone’s job security. Reductions in physician reimbursement, staff salaries, and positions may result, causing even greater professional dissatisfaction. Medical errors are likely to occur more frequently, errors that further compromise patient care and reduce patient outcomes. The emotional and financial costs to patients, staff members (especially nurses), consultants, managers, and administrators are immeasurable if an EP frequently creates conflict and does not possess the skills to identify his or her contribution, to minimize it, or to resolve it promptly.

**CONFLICT RESOLUTION IN EMERGENCY MEDICINE**

If conflict is a disruptive yet inevitable force in EM, conflict resolution and the skills necessary to achieve it are key factors for favorable patient care. Conflict management starts with effective communication among parties. Successful conflict resolution therefore requires parties to demonstrate a willingness to listen fully to the concerns of each other, without interrupting or planning a reply. Expressing a willingness to find common ground may help resolve conflict or at least de-escalate it. A healthy approach to conflict resolution includes treating the other person with respect, active listening (e.g., paraphrasing, demonstrating understanding), and clarifying one’s own needs and perspective.

Conflict resolution for today’s interactions is crucial to tomorrow’s triumphs because future conflict is inevitable. Individuals likely adapted their approach to conflict management based on what “worked” for them in childhood, or from observing mentors. Conflict itself is not necessarily problematic, but how individuals (or organizations) deal with it may be. Five distinct responses to conflict can be plotted using the axes of assertiveness (the extent that individuals attempt to satisfy their own concerns) and cooperativeness (the extent that individuals attempt to satisfy the concerns of others) (Fig. 209.1). Each of these responses to conflict or approaches to resolving it has advantages and disadvantages and circumstances when it may prove effective or ineffective. For example, an EP preferring the accommodative style (low assertiveness and high cooperativeness) may have poor patient outcomes over time. The competing style employed by many EPs may create quick results necessary for patient care, but it is unpopular.

Although most complex, the collaborating style is the method to adopt whenever possible. Its outcome generally causes both sides to win. Collaboration is one of the main tenets of principled negotiation. Characterized by high assertiveness and high cooperativeness, this style is best used for learning, integrating solutions, and merging perspectives. Exploring issues in depth and confronting differences often result in increased commitments and improved relationships among involved parties. Despite the time constraints of EM, the collaborating style can be integrated into patient care activities by an EP and used successfully in conflict resolution.
Conflict resolution in EM has a critical role with respect to patient care, as well as positive interpersonal and group relations. Successful communication is integral to promoting positive interactions among individuals, in an effort to prevent (or minimize) conflict before it becomes detrimental. Poor communication among individuals may potentiate ongoing conflict and misunderstanding. Building alliances with colleagues may reduce the likelihood and amount of conflict. Team building within the ED and hospital, to promote constructive, creative, and cooperative approaches to conflict management, is vital to success.

**CHALLENGES TO CONFLICT RESOLUTION**

> EPs take for granted that difficult interactions occur as part of their daily experience. Some EPs may not find conflict particularly challenging or stressful. Successful EPs must be leaders within the ED, even if outside staff members are uncomfortable with their leadership style. This may be particularly true during stressful situations, when EPs gravitate toward the competing style of conflict resolution. Individuals who seldom use the ED (e.g., patients, families, consultants, hospital administrators) may not be comfortable with the environment or its interactions because its structure and culture are “foreign” to them. Unfortunately, the ED does not always provide the kind of service that health care professionals have come to expect. For example, a surgeon in the operating room has instruments handed to him or her in exactly the way he or she prefers by a designated individual. This is done in both the patient’s and the surgeon’s best interests. In the ED, however, staffing shortages or more pressing cases may cause a consultant to be “ignored.” This situation often results in problems for everyone because consultants may take their frustration out on EPs or ED staff. Conflict within the ED is the likely outcome.

**STRATEGIES FOR SUCCESSFUL CONFLICT RESOLUTION**

With all this conflict occurring in the ED, successful EPs apply strategies to reduce or resolve it, to preserve the best possible patient and provider satisfaction without compromising patient care. Drs. Marco and Smith described 10 reasonable principles for conflict resolution in EM (Box 209.2). EPs should make it their “standard of care” to refrain from hostile communication and instead persuade others using kindness and intellect, focusing on patient advocacy and safety.

O’Mara focused on the interrelationship between communication and conflict resolution. She wrote that “each relationship presents its own potential for ongoing communication dynamics, which may include conflict and misunderstanding” and added that “appreciating alternative viewpoints and a willingness to adapt are prerequisites for managing interpersonal conflict.”

**RELATIONSHIPS IN THE EMERGENCY DEPARTMENT**

Certain unique aspects of the EP-patient interaction may lead to conflict. First, the nature of this interaction is new, intense,
unexpected, brief, and unselected. Neither the patient nor the 
EP chose the other. Furthermore, the balance of power in any 
doctor-patient relationship is unequal. Each participant has a 
different perspective on the nature of the emergency condi-
tion. Anxiety, pain, cost of care, lost wages, disability, morbid-
ity, and mortality are of great concern to patients. Furthermore, 
the timing of care—how long is appropriate to wait for pain 
relief, test results, consultants, an admission bed, or discharge 
instructions—creates conflict (and at times open hostility). In 
these situations, mismatched expectations and perspectives 
between a patient and an EP result in conflict that can be 
intensified by stress, pain, and social, cultural, and language 
differences.

EPs have numerous interactions with nursing that must be 
successful as often as possible even though they occur under 
stress. Positive or negative exchanges between physicians and 
nurses are likely remembered during subsequent interactions; 
nurses typically interpret an EP’s words, communication style, 
and body language in the context of prior interactions. 
Research clearly demonstrates that the doctor-nurse relation-
ship has a significant impact on patient care.

Conflict resolution between EPs and staff members may be 
difficult to achieve, especially if interactions occur infre-
quently. In almost all situations, the earlier and more directly 
problem interactions are addressed, the more likely it is that 
future interactions and outcomes will be positive. These dif-
ficulties should be addressed in a nonthreatening, collegial, 
and supportive environment, in addition to removing personal 
issues from the problem. If this approach is neither possible 
nor successful, a skilled, unbiased outsider may be needed 
(particularly if differences in age, gender, cultures, ethnicity, 
rank, or position exist).

Additional strategies to foster successful conflict resolution 
in EM include social or educational meetings with colleagues 
and staff outside the ED. EPs who participate in medical staff 
affairs or who serve on hospital committees share time with 
colleagues when stress is not maximal. Positive interactions 
and sharing of common interests during these activities are 
likely to build alliances that may reduce the amount and inten-
sity of conflict. This strategy will almost certainly improve 
conflict resolution in the future.

The book Getting to Yes describes using principled negotia-
tion, which decides issues on their merit to resolve conflict, 
rather than through a haggling process focused on what each 
side says it will and will not do.6 This method suggests looking 
for mutual gains whenever possible. When interests conflict, 
individuals should insist that the result of negotiation be based 
on fair standards, independent of the will of the other side.

Preparation is an important element before negotiations 
begins, although this is sometimes difficult in EM. Several 
opportunities exist to increase preparation before consultation 
(which is a negotiation). Making efforts to have the patient’s 
identifying information available at the start of the conversa-
tion, reviewing the laboratory and radiographic results before 
the call if possible, and clearly stating specific goals of the 
contact help reduce conflict before it occurs. Communicating 
in the consultant’s language and refraining from making sug-
gestions (even obvious ones) unless asked are excellent 
strategies.

Getting to Yes recommends that negotiators develop their 
best alternative to a negotiated agreement (BATNA), which 
serves as the basis for exploring and evaluating options.5 This 
approach involves thinking carefully about what would happen 
if a negotiated agreement cannot be reached, while simultane-
ously serving as an impetus to engage in a process with agree-
ment as the outcome. Communication that begins with careful, 
empathic listening helps resolve conflict and allows the other 
party to feel heard. Avoiding negative comments or ridicule 
(especially public) and depersonalizing the conflict are healthy 
approaches to its management. This allows the other party to 
maintain self-esteem and self-respect. Remaining objective 
and maintaining composure while focusing on the issues are 
important. One must be careful when responding to emotions; 
silence can be powerful and may de-escalate conflict.7

**BENEFITS OF CONFLICT RESOLUTION**

Dr. Andrew recommended “paraphrasing the communication 
back to the complainer” and “expressing a willingness to find 
a common ground.”3 These recommendations are critical 
because conflict is often generated (and many times escalated) 
by the fear that a concern was not heard or validated. 
Dr. Andrew described four A’s that assist with conflict 
resolution:

1. **Acknowledge** the conflict (“I understand your concern. I 
can tell you are not pleased with what has taken place.”).
2. **Apologize** (blamelessly) for the situation (“I’m sorry this 
situation occurred.”).
3. **Actively** listen to the concern (“Please go on. I want to hear 
more about this.”).
4. **Act** to amend (“I promise I will act to fix this situation and 
[try] to make certain it doesn’t happen again to someone 
else.”).3

Skillful negotiating techniques embody an empowering, 
active, constructive, and positive approach to resolving diffi-
culties and often yield successful outcomes or incremental 
change over time. Numerous benefits result from successful 
conflict resolution, with short- and long-term impact (Box 
209.3).

**BOX 209.3 Positive Outcomes of Conflict Resolution**

1. Improved communication with patients and colleagues
2. Reduced stress levels and improved staff morale
3. Increased workplace productivity (and possibly reim-
   bursement), with reduced expenditures related to conflict
4. Promotion of healthy relationships with colleagues and 
   staff
5. Improved patient, staff, and physician satisfaction
6. Decreased staff turnover (increased staff retention)
7. Improved recruitment
8. Prevention of future conflict, or at least resolution of 
   future conflict more effectively and expeditiously
9. Decreased medical error with improved patient safety
10. Improved overall patient care
SUMMARY

Conflict has been described as a natural consequence of incompatible behaviors and unmet expectations. The preferred strategy to manage conflict is to prevent its occurrence, which is not easy in EM. Effective communication among individuals and within groups in which parties are respected and heard produces an environment of trust. This results in the likelihood that conflict will be resolved more effectively. EPs should be aware of their behaviors and styles of interaction that increase conflict in an environment predisposed to conflict. Furthermore, EPs must strive to understand principles of conflict and conflict resolution, including effective communication, strong interpersonal and listening skills, and the tenets of professionalism because they may help achieve successful EM practices (Box 209.4).

BOX 209.4 Comprehensive Approach to Successful Conflict Resolution

1. Accept the existence of the conflict.
2. Focus on the big picture.
3. Separate the person from the problem.
4. Clarify and identify the nature of the problem creating conflict.
5. Deal with one problem at a time, beginning with the easiest.
6. Engage the respective parties in an environment of impartiality.
7. Listen with understanding and interest, rather than evaluation.
8. Validate issues and concerns.
9. Identify areas of agreement; focus on common interests, not on positions.
10. Attack data, facts, assumptions, and conclusions, but not individuals.
11. Brainstorm realistic solutions in which both parties benefit.
12. Use and establish objective criteria, when possible.
13. Do not prolong or delay the process.
15. Evaluate and assess the problem-solving process after implementing the plan (follow up periodically).

Informed Consent and Assessing Decision-Making Capacity in the Emergency Department

Diane B. Heller

When the patient is a minor, the general rule is that informed consent must be obtained from a parent before a physician may proceed with nonemergency treatment. However, EMTALA (Emergency Medical Treatment and Active Labor Act) permits a physician to evaluate every patient, including minors, to assess whether an emergency medical condition exists and to stabilize any such condition. Many exceptions exist to the general rule of parents consenting for their minor children. For example, a minor may have the ability to consent to treatment of sexually transmitted diseases or drug addiction. These exceptions vary from state to state, however, so it is important to be familiar with the local laws where you practice.

Today, in the absence of a recognized exception to the requirement for informed consent, failure to obtain consent properly may also result in liability under the legal theories of privacy or negligence. In the emergency department (ED), we often find ourselves in circumstances in which the so-called emergency exception applies. The emergency exception states that consent is implied in cases in which an immediate threat to the life or health of the patient exists, when the proposed treatment is necessary to address the emergency condition, and when one is unable to obtain express consent of the patient or someone authorized to consent on the patient’s behalf. In these instances the EP may presume that the patient would consent to the emergency treatment, and the EP does not need to obtain express consent before proceeding with treatment.

Informed Consent

BACKGROUND

The concept of informed consent is based on both ethical and legal obligations that have evolved over the past century. The ethical foundations of informed consent are that the physician must strive to balance the goals of acting in the best interest of the patient while respecting the patient’s autonomy to decide what is best for his or her own body. Currently, informed consent requires an active role on the part of the patient, as well as respect for the patient’s wishes by the emergency physician (EP).1

The legal foundation of informed consent centered initially on protection of the patient from battery or unwanted touching. In 1914, Justice Cardozo succinctly stated that “Every human being of adult years and sound mind has a right to determine what shall be done with his own body.”2 The presumption is that every adult has the right to accept or decline recommended treatment from a physician.

ELEMENTS

To satisfy the requirements of informed consent, three elements must be met. First, the physician must provide the patient with adequate disclosure of information to enable the patient to make an informed decision. Second, the patient must make the decision voluntarily. Finally, the patient must have the capacity to make the decision.

The scope of information to be disclosed is well established in theory but challenging in practice. The physician must disclose (1) the nature of the disease or problem and the nature and purpose of the proposed treatment or procedure; (2) the potential benefits and risks associated with the proposed treatment or procedure, as well as the likelihood that they will occur; and (3) alternative approaches, as well as the benefits and risks of such alternatives.

Fulfillment of the disclosure element in the ED poses several challenges. For example, the time for patient-physician

KEY POINTS

- To respect patient autonomy and abide by the law, the physician must obtain informed consent from a patient before examination and treatment.
- To satisfy the requirement for informed consent, three elements must be present: (1) disclosure of information by the physician must be adequate, (2) the patient’s decision must be voluntary, and (3) the patient must possess decision-making capacity.
- Decision-making capacity is a medical determination made by the treating physician and is specific to the clinical decision at issue.
- The emergency department environment poses unique challenges to determination of decision-making capacity.
- To possess decision-making capacity, a patient must have the ability to (1) communicate a choice, (2) understand relevant information, (3) appreciate the significance of information to the patient’s own individual circumstances, and (4) use reasoning to arrive at a decision.
interaction is often limited in the ED. In addition, a quiet and private setting for discussion is often unavailable. Furthermore, the EP is typically working with limited knowledge about the full scope of the patient’s medical history, intellectual capabilities, and emotional state. It is the EP’s responsibility, however, to minimize the impact of these challenges and to provide information that will maximize the likelihood that the patient will participate effectively in the decision-making process.

The second element, that consent must be given voluntarily, is not as well delineated in the medical literature or by the courts. Although it is obvious that outright threats or forced treatments violate this tenet, there are subtle ways in which a physician may coerce a patient into making a decision that are also unacceptable. For example, if a physician tells a patient that pain medicine will be withheld until the patient agrees to undergo a computed tomography (CT) scan, the voluntary nature of the patient’s decision will be compromised. Additionally, the physician cannot withhold or distort information to alter a patient’s decision. The physician must present information in a way that aids the patient in making the decision and leaves the patient feeling that he or she has an actual choice in the matter.

The final element—and the focus of the remainder of this chapter—is that the patient must possess decision-making capacity. Decision-making capacity refers to a patient’s ability to participate in and make a meaningful decision regarding diagnosis and treatment. The treating physician must determine whether the patient is able to make a specific decision regarding his or her medical care. However, the physician must start with the presumption that an adult patient has the capacity to give informed consent and, absent evidence to the contrary, health care decisions should be deferred to the patient. If the physician determines that the patient lacks the capacity to make medical decisions, the physician must then determine how to proceed. If the patient has specifically expressed health care wishes through an advanced directive, these wishes should be honored. Similarly, if the patient has designated an individual to make health care decisions for him or her, that person should be contacted to make decisions on behalf of the patient. In other instances, family members should be contacted to help make health care decisions.

Although psychiatric consultation may be helpful in assessing decisional capacity in patients, it is not required. Formal legal procedures also exist to assist in the determination, but evaluations of capacity are routinely made without recourse to the court system. The process is usually performed solely by the treating EP in the ED. Indeed, the EP assesses decision-making capacity as part of routine interactions with every patient treated.

**DECISION-MAKING CAPACITY**

*Decision-making capacity* is a clinical term that is specific to the particular medical decision at issue. If the physician determines that the patient lacks decision-making capacity, the patient can be denied the right to make meaningful decisions regarding his or her medical care.

To possess decision-making capacity, the patient must exhibit the following four abilities: (1) to communicate a choice, (2) to understand relevant information as it is communicated, (3) to appreciate the significance of the information to his or her own individual circumstances, and (4) to use reasoning to arrive at a specific choice. When patients cannot demonstrate these abilities, they lack the capacity to give informed consent for their medical care.

In all instances the physician must balance the interests of protecting the patient from harm while respecting patient autonomy. The level of scrutiny that a physician applies to evaluating capacity therefore varies depending on the decision to be made and the risks and benefits of the proposed medical care. For example, if a patient with a superficial abrasion refuses the application of a bandage, the EP should exercise a very low level of scrutiny when assessing the patient’s capacity to make decisions. If the same patient, however, refuses a CT scan after head trauma with prolonged loss of consciousness, the EP should scrutinize the patient’s capacity at a much higher level. This general approach to evaluating decision-making capacity is often referred to as the sliding scale model. Determination of capacity can be made only with reference to the particular facts surrounding an individual decision by the patient; as the risks associated with a decision increase, the level of capacity needed to consent to or refuse the intervention also increases.

**WHEN TO EXERCISE ADDITIONAL CARE IN ASSESSING CAPACITY**

Assessing a patient’s decision-making capacity is an implicit part of every medical encounter in the ED. The process is generally spontaneous and straightforward and takes place as the EP examines and talks with the patient. The EP’s starting point is always the presumption that an adult patient has the requisite capacity to consent to or refuse medical treatment. Under certain circumstances, however, a more detailed and direct inquiry into a patient’s decision-making capacity must be performed (see the “Red Flags” box). Although no accepted rules exist regarding when the EP must delve more deeply into this issue, certain situations should alert an EP to the need to assess a patient’s decision-making capacity more carefully.

---

**RED FLAGS**

*Signs That a More Careful Evaluation of Capacity Might Be Warranted*

- Patients who refuse recommended treatment (especially if they refuse to discuss their decision)
- Patients with a change in mental status
- Patients who frequently change their mind or make inconsistent decisions
- Patients with known risk factors for impaired decision making, such as the following:
  - Chronic psychiatric or neurologic conditions
  - Cultural or language barriers
  - Educational-level concern or developmental delay issues
  - Significant stress, anxiety, or untreated pain
  - Extremes of age: older than 80 years because of an increased risk for dementia; younger than 18 years because of a potential need for parental involvement
The most common situation that triggers a more detailed inquiry into a coherent patient’s decision-making capacity occurs when the patient chooses a course of treatment contrary to the one recommended by the EP or refuses treatment entirely. Simple disagreement with an EP’s recommendation, however, is not grounds for declaration of a lack of capacity. If the EP believes that the patient’s choice is not reasonable, it may trigger the start of an inquiry, but it is not the end of the inquiry. As discussed earlier, refusal of treatment is more worrisome if the consequences of the patient’s decision are great. Furthermore, if the patient is unwilling to discuss the reasons behind his or her refusal, the EP should be even more concerned about performing a careful evaluation of the patient’s decision-making capacity before simply accepting the patient’s choice.

A second general area that should raise the EP’s concern regarding decision-making capacity is when a patient has an abrupt change in mental status. Although the reasons for the change in mental status may be as varied as infection, stroke, head trauma, or ingestion of mind-altering substances, the result is the same. The EP is under an obligation to conduct a more careful evaluation of the patient’s capacity to participate in decisions on medical care. The simple existence of a change in mental status, however, does not automatically preclude a patient from possessing the requisite capacity. It is simply a situation that should trigger the EP to make a more detailed inquiry.

A third broad area that should prompt the EP to evaluate the patient’s capacity more carefully is the presence of a known risk factor for impaired decision making. Risk factors may include known psychiatric conditions such as severe depression or schizophrenia. Although the presence of mental illness does not automatically preclude a patient from having the right to participate in his or her medical care, in such an instance it may be helpful to seek the opinion of a psychiatrist. If cultural or language barriers are present or if concerns exist about a patient’s level of education, the EP should also exercise heightened scrutiny of the patient’s decision-making capacity. In these instances the EP must take steps to compensate for these factors to ensure that the patient has the greatest opportunity to participate in his or her medical care. The EP should arrange for a translator when necessary and should take additional time to explain the issues in terms that the patient can more readily understand. Extremes of age are also known risk factors for impaired decision making. Although not every patient over a certain age exhibits dementia, the EP must be aware of the increased prevalence of this condition in elderly patients. Other common risk factors in the ED are extreme pain, stress, and anxiety, each of which can impair a patient’s ability to receive or process information.

Although the foregoing situations are by no means all-inclusive, they represent instances that should put an EP on notice that a more careful and detailed evaluation of capacity may be needed. Again, none of these circumstances will alter the presumption that an adult possesses the requisite capacity to participate in his or her medical care. They simply mark the need for a more detailed inquiry. In each of these instances the EP should take additional care when documenting the care of the patient, as well as his or her interactions with the patient. Specifically, the physician should document any evaluation that is conducted of the patient’s capacity (see the “Documentation” box).

**SUGGESTED QUESTIONS TO AID IN THE DETERMINATION OF CAPACITY**

The final determination of a patient’s decision-making capacity depends on whether the EP believes that the patient exhibits the four abilities required for capacity: (1) to communicate a choice, (2) to understand relevant information as it is communicated, (3) to appreciate the significance of the information to his or her own individual circumstances, and (4) to use reasoning to arrive at a specific choice. Thus the EP’s inquiry should consist of focused questions to evaluate each of these areas (see the “Tips and Tricks” box).

The first requirement, communicating a choice, can be evaluated simply by asking the patient what he or she wants to do. Stability of the choice is also important. Although this may not be a factor given the urgency of many procedures in the ED, if the proposed treatment or procedure will not occur immediately, the EP should confirm that the patient’s choice remains the same after a certain period. If, for example, patient A agrees to a lumbar puncture for his headache, the EP can simply confirm the patient’s decision after preparations for the procedure have been made.

To test the patient’s ability to understand relevant information, the EP may start out by simply asking the patient to paraphrase what he or she has been told. Patients should use their own words and not simply parrot back the information recited by the physician. The EP can also ask pointed questions such as “What is your understanding of your condition and the options that we have discussed?” Patient should be able to explain, in their own words, the nature of the condition, the available options, and the risks and benefits of these options. This includes their understanding of what will happen if they do nothing. In the foregoing example of a lumbar puncture, patient A needs to understand the risks of the procedure, as well as the possibility that a negative CT scan without a negative lumbar puncture may mean that he still has a life-threatening condition.
Questions to Ask Patients to Facilitate the Determination of Decision-Making Capacity

The ability to communicate a choice:
- Have you decided what you want to do?
- We have discussed many things; have you made a decision?

The ability to understand relevant information as it is communicated:
- What is your understanding of your medical condition?
- What are the possible diagnostic tests or treatments of your condition?
- What are some of the risks of the options that we have discussed?
- How likely is it that you will have a bad outcome?
- What could happen if you choose to do nothing at this time?

The ability to appreciate the significance of the information to one’s own individual circumstances:
- Why do you think your doctor has recommended this specific test or treatment for you?
- Do you think that the recommended test or treatment is the best option for you?
- Why do you think that this is the best option for you at this time?
- What do you think will happen if you accept (or refuse) this option?

The ability to use reasoning to arrive at a specific choice:
- Why have you chosen the option that you did?
- What factors influenced your decision?
- What weight did you give to these different factors?
- How do you balance the positives and negatives (or risks and benefits)?

To satisfy the third element of decision-making capacity, the EP must be sure that patients understand how the information discussed relates to them as an individual. The EP can ask patients whether they think that the proposed option is the best option and why. The EP should also explore what patients think will happen in the future if they choose the proposed option. Using the foregoing example, this may be as simple as the fact that patient A will need to spend several hours in the ED waiting for the results of the lumbar puncture or that he may experience a postprocedural headache that will interfere with work the following day.

To evaluate the patient’s ability to reason, the EP should ask the patient why he or she has chosen a specific option. The EP can inquire what factors influenced the patient’s decision and what weight was given to these factors. In the foregoing example, patient A may tell the EP that he cannot wait for a lumbar puncture after the CT scan because he has to pick up his daughter after school or that he has had similar headaches in the past and therefore thinks that this headache is not serious. Alternatively, patient A could tell the EP that he believes that when the procedure is performed, the EP will inject radioactive material into his body because the EP is trying to kill him. Sometimes simple questions yield very complex and interesting answers that can aid the EP’s determination of capacity.

In addition to asking focused questions relevant to capacity, the EP has the option of obtaining a consultation from a psychiatrist if time allows. Although no requirement mandates that a psychiatrist be involved, it may be helpful in certain circumstances. First, it can never hurt to obtain a second opinion when making a determination of capacity. Second, psychiatrists are skilled at interviewing patients. Third, they are experts in diagnosing mental illnesses that may impair a patient’s decision-making ability. Involvement of a psychiatrist does not relieve EPs of their responsibility to take part in determination of capacity. Decision-making capacity relies on the communication of adequate medical information that is unique to the patient’s condition and proposed treatment. Only the treating EP can ensure adequate disclosure of this information, and the EP cannot delegate this task to a psychiatrist.

CONCLUSION

In every encounter in the ED, it is the treating EP’s responsibility to ensure that the patient gives informed consent for medical care. This consent must be given voluntarily by a patient with the requisite decision-making capacity, and the patient must receive adequate information to make the decision. Although some evaluation of decision-making capacity is an inherent part of every patient-physician encounter, certain situations should alert the EP to the need for a more detailed inquiry. To this end, the EP should ask questions in the clinical interview that specifically address the requisite elements of capacity.

Regulatory and Legal Issues in the Emergency Department

Paul D. Biddinger

**KEY POINTS**

- Individual states have the authority to regulate the practice of emergency medicine within their borders. The state public health department generally administers this authority.
- The Joint Commission is a private organization with a mission to improve the safety and quality of medical care. Although participation in the accreditation program is voluntary, most hospitals in the United States seek Joint Commission accreditation, and therefore most emergency departments are subject to its standards.
- Certain federal laws, such as the Emergency Medical Treatment and Active Labor Act (EMTALA) and the Health Insurance Portability and Accountability Act (HIPAA), create additional obligations for emergency departments and physicians. Emergency physicians can place themselves at significant legal and financial risk if they are not aware of these obligations.
- EMTALA requires emergency physicians to provide appropriate screening and stabilization for all patients seen in their institutions with an emergency complaint. EMTALA further regulates access to “on-call” specialists, as well as transfer of patients between health care facilities.
- HIPAA has changed the way in which physicians and hospitals collect, store, and share health information. Although the regulations are complex, physicians can best adhere to the regulations when they access or share health information only on a “need-to-know” basis and attempt to obtain the patient’s permission for sharing such information whenever possible.
- Most states have special reporting requirements for victims of child abuse and certain infectious diseases. Some states have additional requirements, such as to report victims of other violent crimes, patients who seize and have a driver’s license, or animal bites. Emergency physicians should be familiar with the reporting requirements in the jurisdiction in which they practice.

**BACKGROUND**

The medical care delivered in the emergency department (ED) is subject to a significant number of local, state, and federal regulations, as well as nongovernmental standards, that are designed to ensure quality care for each individual, ensure equity in care among all patients undergoing emergency evaluation, and protect vulnerable patients who may not be able to adequately advocate for themselves. Emergency physicians should be aware of the regulatory environment in which they practice because ignorance of these regulations (especially with respect to regulations of the Emergency Medical Treatment and Active Labor Act [EMTALA] and the Health Insurance Portability and Accountability Act [HIPAA]) may place both an individual physician and the institution at significant financial and legal risk.

**PUBLIC HEALTH AUTHORITY**

Each state has the right to license and regulate both the health care facilities and providers within its jurisdiction. Generally, the state public health authority (state health department) administers this right. Even though all emergency physicians are, of course, aware that they, nurses, and other medical professionals obtain their medical licenses from the state department of public health, relatively few know of the extent to which their hospitals and associated departments (e.g., hospital EDs, operating rooms, computed tomography scanners, cardiac catheterization laboratories) must obtain similar permissions to deliver health care or the extent to which hospitals may be subject to review in the event of a perceived or reported problem. In addition to state regulation, hospitals are also generally subject to “Conditions for Coverage (CFC)” and “Conditions of Participation (CoP)” from the Center for Medicare and Medicaid Services (CMS) of the federal government. According to the CMS, the CFC and CoP are the “minimum health and safety requirements that hospitals must meet to participate in the Medicare and Medicaid program.” Although the CFC and CoP are not generally required of hospitals for licensure, hospitals are mandated by federal law to meet the standards if they wish to receive Medicare and Medicaid reimbursement for their services. Because Medicare and Medicaid funding is a substantial part of most hospitals’ revenue, most hospitals adhere to the CMS CFC and CoP regulations, as well as those of the state health department.

Because the responsibility to regulate and monitor health care institutions is so great, most states and the CMS share, delegate, or “deem” some portions of this regulatory authority to national expert organizations to help them oversee the quality of health care delivered in their state. The most visible of these expert organizations is the Joint Commission, formerly known as the Joint Commission on Accreditation of Medicine.**
Healthcare Organizations (JCAHO). Other organizations to which states frequently delegate regulatory authority include the American College of Surgeons, which sets standards for trauma centers, and the American Burn Association, which sets standards for burn centers. In addition to delegating portions of their authority to national organizations, state departments of public health may also delegate portions of their authority over health care institutions to local public health officials. One example is the receipt of reports of suspected or confirmed cases of reportable communicable disease.

In no case does any sharing of authority supersede the state’s ability to regulate and oversee health care quality. Indeed, although some states and the CMS recognize Joint Commission accreditation as evidence of meeting acceptable standards, both states and the CMS can always perform their own inspections of facilities, in addition to the Joint Commission surveys. Furthermore, whenever there is a question or concern regarding specific care delivered, the state public health authority generally carries out the site inspection and investigation on its own.

THE JOINT COMMISSION

The Joint Commission is a private, not-for-profit organization. Its mission is to “continually improve the safety and quality of care provided to the public through the provision of health care accreditation and related services that support performance improvement in health care organizations.” Broadly, the Joint Commission sets standards that hospitals must meet to receive accreditation (and generally, by extension, licensure from the state) and receive funding from the CMS. These standards cover a broad range of subjects from patient rights, to patient care, to infection control. The Joint Commission also integrates outcomes and other performance measures into its standards. To maintain their accreditation, health care organizations must undergo a site survey by Joint Commission staff every 3 years. Laboratories must undergo a site survey every 2 years for the same accreditation.

Over the years the Joint Commission has created a number of special programs and work groups with particular relevance to the ED, including groups specifically examining ED overcrowding and hospital emergency preparedness. The most overarching of the Joint Commission programs related to the ED is the set of National Patient Safety Goals (Table 211.1). These goals have been revised and expanded over the years to appropriately reflect the changes in clinical care that have evolved, as well as to address systemic sources of error in medications as they are identified.

Although many departments and practitioners frequently see the Joint Commission requirements as a burden, especially at the time of their site visit, it is important to remember that the purpose of the requirements is to enhance patient safety and reduce opportunities for error. By developing programs that satisfy the Joint Commission requirements, EDs and individual physicians will decrease their risk for adverse events and better mange their medical liability.

Two specific programs that institutions are required to use to help them achieve the national patient safety goals are the “do-not-use list” and the “universal protocol.” The universal protocol was developed by The Joint Commission to prevent “wrong site, wrong person, wrong procedure” surgery and is required of accredited institutions. Although the universal protocol has clear safety benefits for some of the patients cared for in the ED, many emergency physicians remain uncertain of which specific procedures require use of the universal protocol. Even though it is difficult to conceive that repair of a laceration or emergency intubation could be

performed on the wrong limb or wrong patient, it is possible that tube thoracostomy, lumbar puncture, or central venous cannulation (among other procedures) could be performed in the ED on the wrong patient, especially when a patient’s visit spans different shifts or when consultation services are requested to perform procedures. Thus, for the appropriate circumstances and procedures, EDs must develop and use a universal protocol that includes provisions for a hard-stop “timeout” in which the physician and nursing staff stop to ensure that informed consent has been given, that the procedure is warranted, and that it is performed on the correct patient at the correct site before selected procedures are performed.

The do-not-use list is a compilation of medical abbreviations that have been identified as the most likely sources of error found when orders are either miswritten or misinterpreted (or both) (Table 211.2). The growing use of computerized order entry systems and computerized prescription writing programs is likely to decrease the number of these types of errors; however, physicians who write handwritten orders must be familiar with the prohibited abbreviations, and departments should bar them from use in clinical practice.

* Applies to all orders and all medication-related documentation that is handwritten (including free-text computer entry) or on preprinted forms.
† Exception: A “trailing zero” may be used only when required to demonstrate the level of precision of the value being reported, such as for laboratory results, imaging studies that report size of lesions, or catheter or tube sizes. It may not be used in medication orders or other medication-related documentation.
‡ For possible future inclusion in the official do-not-use list.

**EMERGENCY MEDICAL TREATMENT AND ACTIVE LABOR ACT**

One of the most confusing, misinterpreted, and misquoted set of regulations in emergency medicine is EMTALA. Even the name itself can be confusing because the regulations are sometimes inexact referred to as “COBRA,” which refers to the broader Consolidated Omnibus Reconciliation Act in which the original EMTALA statutes were enacted. First enacted in 1986 and significantly revised in 2003, EMTALA originated as a response to several well-publicized allegations of patient “dumping” in which patients were alleged to have been turned away or transferred from EDs without appropriate care. Broadly, EMTALA creates two major requirements for hospitals that have a dedicated ED and participate in CMS programs. First, patients who “come to” the emergency department and request care must receive an appropriate medical screening examination. Second, for patients with an identified “emergency medical condition,” the emergency physician must either provide appropriate stabilization or arrange transfer to another facility and meet several additional specific requirements pertaining to the transfer. Although
EMTALA applies to hospitals that receive CMS funding, it applies to all patients, not simply those with Medicare or Medicaid insurance.

The first requirement under EMTALA, the “medical screening examination,” must be provided to all individuals who go to the ED requesting an evaluation for a medical condition. Although the specific components of this examination remain ill defined, it is generally agreed that an examination should be performed so that the clinician can say with “reasonable clinical confidence” that an emergency condition is not present that may place an individual’s health (or the health of an unborn child) in serious jeopardy, seriously impair body functions, or represent serious dysfunction of body organs. Furthermore, this medical screening examination must be provided without regard to the ability to pay, insurance status, race, citizenship, or gender.

The second requirement under EMTALA is to provide appropriate stabilization for an emergency medical condition, once identified. In general, this means that an appropriate level of medical care must be provided in the ED or in the hospital (or in both) for the acute medical problem of the patient, again without regard to the ability to pay, insurance status, race, citizenship, or gender. This provision of EMTALA also has implications for on-call physicians. As part of Medicare, hospitals must maintain on-call physicians who are able to provide the medical services needed to treat an emergency medical condition after the medical screening examination. Although the list of on-call physicians is not required by Medicare to be comprehensive, the specialties represented in the on-call list must be appropriate to best meet the needs of its patients within the hospital’s capability. If a hospital does not maintain an appropriate on-call roster or if an on-call physician does not show up to care for a patient with an unidentified emergency medical condition within a reasonable amount of time, that hospital and the on-call physician may be liable under EMTALA statutes.

In the event that the ED or the hospital (or both) are unable to provide appropriate stabilization, EMTALA allows transfer of patients from one facility to another under certain, very specific conditions. First, the patient must request the transfer and a physician must state in writing that the medical benefits of the transfer outweigh its risks. Second, the hospital that receives the transferred patient must be “appropriate” and have both the space and qualified personnel to treat the emergency medical condition (Box 211.1).

Penalties for violations of EMTALA statutes can be significant for both the physician and the institution. Both the

---

**BOX 211.1 Key Provisions of the Emergency Medical Treatment and Active Labor Act**

Anyone who goes to the main hospital property with an emergency medical complaint must receive a medical screening examination and appropriate stabilization.

Hospitals must maintain appropriate on-call lists of specialists to care for identified emergency medical conditions.

Patients may not be transferred from a higher level of care to a lower level of care.

All patients transferred from one facility to another must be accepted by a physician at the receiving facility before transfer.

When transferring a patient to another hospital, the responsibility to choose the appropriate means of transport (i.e., private vehicle, basic life support, advanced life support, critical care transport) lies with the sending physician.

Institutions with specialty care services must accept transfers from hospitals without such services, provided that they have the space and capability at that time to deal with the patient’s needs.

Patients with an emergency condition must be stabilized before transport to another facility except if (1) the receiving facility has specialty services that the sending facility lacks and the benefits outweigh the risks of transfer and (2) the patient requests the transfer and understands the risks.

Patients may refuse transfer from one facility to another.

---

**TIPS AND TRICKS**

**Medical Screening Examination**

- Must be performed on all patients without regard to their ability to pay
- Must be performed before financial interview
- Not the same as triage
- Must be performed by a medical professional granted authority by hospital bylaws
- Must be sufficient to rule in or rule out an emergency medical condition

**RED FLAGS**

**Emergency Medical Condition**

Acute symptoms

- May result in serious injury or impairment of function to an organ or body part if not treated immediately
- Could jeopardize the health of the patient or unborn child
- Includes severe pain, psychiatric disturbance, active labor, and substance abuse, among others

**HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT**

HIPAA was initially enacted in 1996 in an attempt to make it easier for individuals to transfer their medical records and health care coverage and also to provide greater accountability among providers to limit fraud. Subsequent federal rules defining privacy standards under HIPAA have substantially
changed the way in which health care providers and health plans collect, store, and share health information.

Health care providers, institutions, health plans, and health care clearinghouses are all required to conform to HIPAA standards. Accordingly, they are all known as "covered entities." Broadly, HIPAA standards require that all covered entities have appropriate policies and procedures in place to ensure the privacy of all personally identifiable health information that they store and also that personally identifiable health information be shared only with the patient's permission and only in appropriate circumstances. Being covered entities under HIPAA means that health care providers, institutions, and health plans may share health information with one another, when appropriate, without needing to verify the privacy protection of one another. Each covered entity is assumed to have appropriate electronic and physical access controls to patients' medical records and electronic data and to conduct routine audits of its data security procedures.

From the perspective of the emergency physician, HIPAA means that personal health information should be obtained or accessed only when it is relevant to immediate care of the patient. Furthermore, personal health information should be disclosed only to other covered entities and only with the patient's permission. Sanctions for violating HIPAA standards include civil and criminal penalties with fines of up to $250,000 or imprisonment for up to 10 years (or both) for knowingly misusing a patient's identifiable health information.

**SPECIAL CIRCUMSTANCES**

**MANDATORY REPORTING**

Most state public health authorities have mandatory reporting requirements designed to protect vulnerable members of society. Some types of mandatory reporting have to do with the characteristics of the victim. The most common mandatory report of this type is a suspected case of child abuse or neglect. In addition, some states also mandate reporting of suspected elder abuse or abuse of the mentally handicapped. Other types of mandatory reporting have to do with the characteristics of the event. The most common type of this mandatory report is the requirement that health care providers contact police when treating victims of gun violence. Other examples of mandatory reporting may include knife injuries, unusual infections, animal bites, or major burns. Sexual assault represents a unique circumstance in which frequently health care providers are required to report that they treated the victim of such a crime but are not required to report the identity of the patient. This is because it is generally believed that mandatory reporting of individual identities would discourage some victims of sexual assault from seeking medical care.

**SEXUAL ASSAULT**

In addition to reporting certain types of injuries and certain forms of mistreatment, emergency physicians should also be aware of the regulations and procedures in their environment with respect to collection of possible evidence of crimes. Use of an evidence "kit" for a sexual assault victim is commonplace across the country, but procedures for maintaining the chain of custody of the kit and its ownership can vary substantially. Moreover, the manner in which clothes, valuables, and other items removed from a victim of violence are collected, stored, and transferred to law enforcement personnel can have a significant impact on the legal outcome of a case. Emergency physicians should generally be familiar with the basic principles of how to properly handle and store such potential evidence.

**TIPS AND TRICKS**

Know the relevant public health regulations and reporting requirements in your area.

Understand that patient safety initiatives and Joint Commission requirements generally improve care for patients, decrease the chance of error, and therefore decrease emergency physicians' overall medical-legal risk.

Develop mechanisms to perform medical screening examinations on all patients encountered in the emergency department in a timely manner.

Ensure that patients transferred between health care institutions (1) have an accepting physician at the receiving institution, (2) have a signed consent form for transfer when possible, (3) are sent with complete copies of their medical record and any relevant radiographic images, and (4) are transferred by staff with the appropriate level of training and monitoring capability.

Access protected health information only when it is directly relevant to the medical care that you provide.

Be sure to obtain written permission whenever possible when sharing protected health information.

Use caution when restraining patients or preventing them from leaving the emergency department. Make sure that such decisions are supported by the appropriate regulations, careful clinical documentation, and written medical orders.

---

**BOX 211.2 Health Insurance Portability and Accountability Act**

Requires institutions and providers to develop policies and procedures to protect patients' unique health information

Allows institutions and health care providers to use protected health information for treatment, payment, and normal health care operations with minimal restrictions as long as patients consent to its use

Requires written permission for any use of protected health information outside normal health care operations

Gives patients the right to access, copy, and amend their health record

Allows certain health information to be disclosed without the patient's consent only under very narrowly defined conditions (e.g., for public health reporting)

Provides significant penalties for violations

---

---
RESTRAINTS
Finally, the manner in which patients with acute psychiatric complaints such as suicidality, homicidality, or psychosis are monitored and restrained in EDs is generally regulated by the state health authority. Use of physical or chemical restraint in a manner inconsistent with state laws or regulations can expose providers to significant liability. Emergency physicians should always carefully document the reasons for such restraint and the reasons why less restrictive measures could not be used or were insufficient. In some states, in addition to writing the appropriate medical orders to support their decisions, emergency physicians may need to complete specific forms when either physically or chemically restraining a patient or when preventing a patient from leaving the ED for safety concerns.

**Medical-Legal Issues in Emergency Medicine**

**Gregory L. Henry and Geetika Gupta**

**Box 212.1 Rules for Physician-Patient Interactions**

It does not matter how long they waited; it was too long. Never argue with patients over the amount of time that they waited. Never use excuses, such as you are working short staffed or “I’ve been here all day.” Apologize for the wait. As soon as you have apologized for the wait, you have at least acknowledged that the patient’s time is as valuable as yours and you understand that waiting is not a comfortable situation. Thank the patient the family for coming in. Trivialization of minor complaints can lead to a dissatisfied patient. Most patients believe that they have a legitimate reason to be in the emergency department. To be informed that it is the doctor’s perception that theirs is not an emergency never helps the doctor-patient interaction and does not prevent further emergency department visits.

**DISCHARGE INSTRUCTIONS**

Approximately half the lawsuits in emergency medicine revolve around discharge instructions and the discharge program given to patients. Box 212.3 gives a few paramount rules for discharge instructions.

**UNDERSTANDING THE MEDICAL-LEGAL SYSTEM**

Information on this topic can be found online at www.expertconsult.com

**CONCERNS SPECIFIC TO THE CURRENT-DAY EMERGENCY DEPARTMENT**

The function of this section is to delineate areas where emergency medicine and the law come into direct contact on a regular basis. The emergency department (ED) is under increasing stress to serve and aid the growing number of
uninsured patients. No other specialty in medicine is subjected to laws by the national government to screen and stabilize all individuals entering the ED regardless of their ability to pay for the services.

OWNERSHIP OF PATIENTS
The legal relationship of parties is that the physician is “the retained agent and servant of the patient.” When a patient is in your department, he or she is your patient from a legal standpoint, and thus the physician cannot abrogate responsibility by saying that the patient belongs to another physician.

COMBATIVE PATIENTS
The ED has the duty to restrain patients when they constitute a danger to self or others by virtue of a physical or mental condition (Box 212.4). Determination of mental and physical capacity is the key issue. Patients who lack capacity will depend on the substitute judgment of the EP. Belligerent patients who have capacity require law enforcement to handle the situation.

CIVIL COMMITMENT
Again, the role of the ED is to secure the patient so that the patient does not cause harm to self or others and to fill out a first certification detailing the behavior and physical findings that justify civil commitment.

**BOX 212.2 Legibility and Decipherability**

Handwritten entries on a chart must be legible to the average person. Action can now be brought by hospitals against physicians for poor handwriting.

**Electronic Medical Records**
The electronic medical record (EMR) is legible but often very sparse in the medical decision-making section. An advantage of the EMR is that all entries are time-stamped, thereby giving a better account of the emergency department (ED) visit. Its biggest disadvantage is automated and templated charting. This can be a downfall and cause to question the chart’s accuracy, particularly if obvious mistakes are present.

**Timeliness of Making a Record**
All events and entries made on the chart should be timed. This is critical to fully understand what transpired during the ED visit.

**Address Nursing Charting**
Emergency physicians (EPs) should also routinely read nursing notes during the shift. If there are discrepancies between the EP and nursing assessments, they can be addressed while the patient is in the ED.

**Altering the Medical Record**
Corrections should be made in an obvious and straightforward manner. All additions and corrections to the chart need to be dated and timed. Nefarious correction of the medical chart is now a federal crime.

**Comments on the Chart**
The chart is a legal document protected by both state and federal law. The chart should reflect the objective observations of concerned health care personnel.

**BOX 212.3 Rules for Discharge Instructions**

All instructions should be time specific.
- Time-specific instructions such as “Return in 6 hours for reexamination of your abdomen or sooner if worse” are clear and to the point. The patient knows what to do and when to do it.

Instructions should be action specific.
- Although discharge instructions need to be brief and to the point, they need to provide knowledge to the patient about the disease process. It is important to discharge an informed customer.

Abbreviations in discharge instructions should be avoided.
Instructions should be doctor specific.
- It is preferable that the patient be given names and phone numbers for all the physicians with whom the patient is to follow up.

**BOX 212.4 Rules for Restraining Combative Patients**

Restraint methods should be appropriate.
- Both chemical and physical restraints are still commonly used to control patients who constitute a threat.

The need for restraints must be documented.
- The specific mode of restraint needs to be written as an order, and the patient’s basic personal needs require proper nursing care.

All restrained patients require reevaluation.
- This is done at specific intervals to determine the continued need for restraints.

Emergency physicians rarely become involved legally in restraint cases.
- The exception is battery/assault cases in which they (1) fail to document the reason for restraint and (2) fail to follow their own hospital emergency department’s restraint policy.

- Most states require a second certification process to be done in a specified time frame by a mental health professional.
- Ruling out organic causes of disease is necessary.
- The primary goal of the initial evaluation is to arrange for the patient to be reevaluated by mental health professionals.

**Transfers**
The Emergency Medical Treatment and Active Labor Act (EMTALA) is the rule by which a patient can legally be transferred or discharged out of the ED to another facility. Box 212.5 contains a set of guidelines for complying with the EMTALA.

**REPORTABLE ILLNESSES**
The legal system and the ED function together as essentially an officer of the court. In all 50 states, child abuse, elder abuse, and assaults are reportable conditions. The EP also maintains a duty to third parties who may not be present in the ED. Therefore, when a patient has a gunshot or stab
Chapter 212  Medical-Legal Issues in Emergency Medicine

**Box 212.5 Key Points of the Emergency Medical Treatment and Active Labor Act**

Informed refusal can allow a patient to exempt himself or herself from EMTALA regulations. The emergency physician and the nurse involved in the case should carefully note this on the patient’s chart.

The patient should be stabilized such that the acts of transfer and moving the patient to a higher level of care have a reasonable probability of providing a better outcome for the patient.

A hospital that usually and customarily receives patients should accept these patients unless their capabilities, at that time, are overwhelmed and they are unable to find room. This fact should be noted on the records when trying to procure transfer of a patient.

Failure to comply can lead to hefty fines to the institution and physician.

**Box 212.6 Against Medical Advice**

Patients who leave against medical advice are using a form of informed refusal. The legal process contains the following:

- Document the mental capacity of the patient.
- Provide the patient a diagnosis or potential diagnosis in a form that the patient can understand.
- Explain the risk and benefits of what can happen if the patient does not take the advice of health care workers.
- While being compliant with the Health Insurance Portability and Accountability Act, communicate with family or friends who are with the patient so that they may also be involved in persuading the patient to receive medical care.
- Have a witness, such as a nurse or family member, sign the document.
- Document all of the above.

**LEGAL BLOOD DRAW FOR ALCOHOL TESTING**

This varies from state to state because some states have given the police warrant authority to obtain blood whereas in others a court order is required. It is the ED’s responsibility to comply with the law. The police have the right to discarded body contents (e.g., vomitus, urine, feces) once such material passes into the public domain. An EP is also obligated under the EMTALA to offer a medical screening examination to all individuals arriving for a blood draw.

**INCIDENT REPORTS**

Incident reports are a part of the quality assurance system. In most states, incident reports are protected from both discovery and judicial admissibility. The function of such reporting is to improve care. Incident reports should not be filed in a patient’s chart.

**RESPONSE TO IN-HOUSE EMERGENCIES**

All contracts should be written such that the EP will respond if not required to remain in the ED because of the acuity level of other patients. The hospital always has the alternative of putting a patient on a cot and bringing the patient to the ED. In many states, response to in-house emergencies is considered part of an in-house Good Samaritan statute. This again varies from state to state and should be confirmed by EPs at each site where they are required to perform this duty.

**WRITING ORDERS FOR ADMITTED PATIENTS**

The EP’s medical liability carrier may have questions regarding orders written on already hospitalized patients. The best ways to limit exposure on the writing of inpatient orders are as follows:

- Limit all orders.
- Write only true admitting orders and not continuing care orders.
- Make it clear when Dr. X, the attending physician, assumes care of the patient.

**PRESCRIPTIONS FROM THE EMERGENCY DEPARTMENT**

Any prescription requiring a Drug Enforcement Agency prescription number should have proper warnings documented, usually on the ED general discharge instructions. In addition, one should avoid writing prescriptions for nonregistered patients (i.e., the nurse or technician you are working with). There is no medical liability coverage for this practice.

**MIDLEVEL PROVIDERS, RESIDENTS, AND EMERGENCY PHYSICIAN SUPERVISION**

Midlevel providers (MLPs) practice under the EP’s license. EPs should sign off on charts only after they have been reviewed by them. The EP is ultimately responsible for the actions of the MLP.

All resident work must be supervised if it is to be billed for under any federal program. All violations of this mandate are considered criminal violations of the federal law, and the current act has no exemptions.

**PATIENTS WHO LEAVE BEFORE EXAMINATION OR AGAINST MEDICAL ADVICE OR WHO ELOPE**

The last health care professional to see the patient should write a note about why the patient left and attest that the patient had the mental capacity to make such a decision at that time (Box 212.6).

Elopement is a similar process in which the patient disappears in the middle of a work-up. Document what actions were taken to find the patient. For example:

- Search the ED.
- Have security check the parking and smoking areas.
- Call the patient’s contact phone number.
RETURN VISITS
In emergency medicine, “bounce-back patients” should often be reevaluated as new-visit patients. Disease processes may often become evident only after the second or third visit.

CHANGE OF SHIFT
A note should be made in the chart that the patient’s care was transferred to another physician at a particular time and that discussion was held with this other physician so that he or she is properly engaged in continuing care of the patient. The discharging doctor—the second physician to see the patient—generally assumes the duty to make certain that the patient’s care is complete. Repeating the examination and evaluation of vital signs is recommended before discharge.

LABORATORY STUDIES, RADIOGRAPHS, AND ELECTROCARDIOGRAMS
The ED should have a process to detect what has been ordered and to account for the results received. A system is needed in which each variance in laboratory or radiographic test should be handled within the ED.

HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT
The doctor-patient relationship and patient records are protected by federal law under the Health Insurance Portability and Accountability Act (HIPAA). Protection and release of this information are mandated by the HIPAA. Please refer to Chapter 211 for a more in-depth discussion.

DUTY TO A THIRD PARTY
Various therapies may render a patient incapacitated in some way and thereby place the patient and a third party in danger. Issuing a prescription requiring a Drug Enforcement Agency number means that the EP is accepting some responsibility to inform the patient about use of the drug. Other devices that make the patient incapable of normal functioning (e.g., the use of crutches, eye patches, various splints) may also place the patient and others at risk. Discussion of this situation on the chart is useful should the need to provide defense arise.

MINORS
Emancipated minors are those who live outside the home, provide their own financial support, have borne a child, or make their own life decisions. Such emancipation is given through the act of a probate court. In most states, children who arrive for treatment and who are older than 12 years may have questions of child abuse, substance abuse, sexually transmitted disease, and pregnancy treated without parental consent.

TELEPHONE ORDERS AND TELEPHONE ADVICE
In general, the ED should not give telephone advice. Answering machine devices that advise the patient to come into the ED or to call 911 are often the most useful.

SPECIFIC HIGH-RISK MEDICAL COMPLAINTS
The following is a system-based collection of high-risk situations commonly found in the ED that have caused considerable medical-legal consternation.

BOX 212.7 Orthopedic Conditions
If you think enough of an injury to have it radiographed, you should think enough of it to splint it. One radiograph does not rule out a fracture. The emergency physician should never guarantee that something is not broken.
Calcaneal fracture: Examination of the lumbar spine is indicated.
Spinal fractures in children: The thought process must include the possibility of child abuse.
Traumatic femoral fracture: Other chest, abdominal, and cervical spine injuries must be considered.

BOX 212.8 Eye, Ear, Nose, and Throat Rules
Proper use of a laryngeal mask airway or bag-valve-mask apparatus can frequently control and provide adequate ventilation for patients.
Eye foreign body sensation: Make sure that there is no organic cause of the injury, no retained foreign body, and no contact lens use. Prescribe tetanus toxoid, antibiotics, and close ophthalmology follow-up.
Nasal septal hematoma: Document the presence or absence of a septal hematoma.
Ear cartilage injury: Prescribe antibiotics and timely referral to otolaryngology.

ORTHOPEDICS
It is always wise for the EP to let patients know that this is the beginning of a process. Orthopedic management includes recognition, reduction, retention, and rehabilitation (Box 212.7). The ED is only the first part of what may be a long and complex process.

EYE, EAR, NOSE, AND THROAT OR AIRWAY
Airway, in emergency medicine, is everything. Cases involving the airway are major problems because of the serious neurologic injuries that can result (Box 212.8).

WOUNDS
All wounds seen in the ED are potentially contaminated and have foreign material almost by definition (Box 212.9). Lawsuits in emergency medicine wound management are based on three critical issues: foreign body, nerve injury, and tendon injury.

POISONING
“Accidental poisoning” must be clearly reviewed and the potential for abuse or neglect considered. A patient with an intentional overdose should be placed under suicide precautions while actively treating the patient for the effects of the overdose. An EP may consult with poison control.

PSYCHIATRY
In emergency medicine, the major issue with psychiatry is that the physician must be able to delineate organic disease manifested as abnormal behavior (Box 212.10).
CHAPTER 212  MEDICAL-LEGAL ISSUES IN EMERGENCY MEDICINE

BOX 212.9 Rules for Wound Care

Never guarantee that no foreign bodies are left in a wound. Glass does show on radiographs. Liberal use of radiography in shattered glass–type wounds is advisable. A laceration chart that does not comment on foreign body, nerve, and tendon assessment is probably inadequate. Splint wounds in the hand.

Tendon injuries: Deep wounds should be observed through a range of motion to make certain that the tendon injury is not hidden by soft tissue. Repair of tendons is rarely an emergency procedure. These wounds can be properly irrigated and closed loosely, and tendon repair can be performed later, within a reasonable period.

Nerve injuries: Proper documentation of nerve function and follow-up in a timely manner are needed, but immediate intervention is rarely, if ever required.

Wound infections: Higher-pressure irrigation through a syringe is preferable.

Bite wounds: Immobilization, intravenous antibiotics, elevation, and follow-up in a timely manner is recommended.

Follow-up and suture removal. Arranging for follow-up and suture removal is important. Having the wound rechecked in 48 hours and arranging for proper interventions will essentially go a long way in preventing any legal actions concerning wound infections or retained foreign bodies.

BOX 212.11 Rules for Chest Pain

There is no single description of the pain that rules out a cardiopulmonary source of the complaint. One electrocardiogram and one cardiac marker are not adequate to rule out acute coronary syndrome.

D-dimer is helpful only if negative in a low-risk patient. Do not rationalize normal vital signs.

The emergency physician should not write prescriptions for nitroglycerin. Unstable chest pain is unstable angina until proved otherwise.

Response to a gastrointestinal cocktail proves nothing. It is in no way related to being able to separate myocardial from esophageal disease.

BOX 212.12 Rules for Abdominal Pain

If the patient still has an appendix, it could be appendicitis. The emergency physician should not avoid this discussion with the patient. Repeated evaluations may be the safest and single best test for abdominal pain. A few white blood cells or red cells in urine do not equal a urinary tract infection; there may be some other cause of the problem, such as an inflammatory process or aortic pathology. In elderly patients with new-onset abdominal or flank pain, think aortic disease as an important rule-out diagnosis.

BOX 212.10 General Considerations for Psychiatric Patients

The emergency physician (EP) is ultimately responsible for the patient regardless of the opinions of the consulting psychiatric worker.

The EP should adhere to guidelines of the Joint Commission on restraining and reevaluating patients.

The EP cannot say that a patient is free of organic disease, only that the patient is capable of being evaluated by a psychiatric service.

Abnormal vital signs should not be ascribed to psychiatric disease. Clues to organic disease include unexplained abnormal vital signs, tremors, and abnormal speech patterns.

CHEST PAIN

This condition is still the largest risk issue in emergency medicine. Between 20% and 25% of malpractice funds expended in emergency medicine are related to the complaint of chest pain. The groups of diseases that constitute most of these cases are acute coronary syndromes, aortic dissection, and pulmonary embolism (Box 212.11).

ABDOMINAL PAIN

Lawsuits related to abdominal pain in emergency medicine are highly age and sex dependent because of difficulties in diagnosis. Excellent evidence suggests that up to 50% of the time a patient with a complaint of abdominal pain leaves the ED without a specific diagnosis proved by testing. Short-term follow-up is the key because examination is merely a snapshot of a moving picture. If a patient’s examination shows peritonitis, remember that computed tomography has a 5% to 8% error rate for appendicitis. Clinical judgment should rule (Box 212.12).

BACK PAIN

Evaluation of back pain is a daily occurrence in the ED. More than 6 million annual visits have been reported. The evaluation should be systematic and consider the red flags to warrant imaging for ruling out diagnoses with high morbidity and mortality, including ectopic pregnancy, abdominal aortic aneurysm, aortic dissection, spinal cord compression syndrome, and inflammatory conditions (Box 212.13).

UROLOGIC ISSUES

In emergency medicine, urologic emergencies are few. Diagnoses that require emergency intervention are testicular torsion and sexually transmitted diseases. A patient who is being treated for possible sexually transmitted diseases should be asked about partners and should be informed that these partners will also require evaluation and treatment. It is also fair to warn the patient that the public health department will be involved if cultures are positive. The health department has a duty to third parties who have been involved with the patient.
LEADERSHIP, COMMUNICATION, AND ADMINISTRATION

SECTION XXI

ELEVATED BLOOD PRESSURE
Elevated blood pressure is often found in the ED. Most commonly it is related to the stress or pain of the situation involving the chief complaint. It is not the standard to lower all elevated blood pressure. It is recommended that the absence of end-organ dysfunction be documented and that the patient understand the sequelae of elevated blood pressure. Timely follow-up is recommended to address this issue with the patient’s primary care physician.

HEADACHE EMERGENCIES
Headache is one of the most common chief complaints in emergency medicine (Box 212.14). The EP must consider the possibility of subarachnoid hemorrhage, meningitis, or carbon monoxide poisoning in every patient with headache.

SPINAL CORD INJURY
Spinal cord injuries are relatively rare, but they carry a devastating societal and financial cost. During the patient’s evaluation, the EP should properly document immobilization, and there should be no hurry to remove such immobilization. Document an appropriate neurologic examination on arrival of the patient. Obtain a magnetic resonance image for patients with evidence of motor, bowel, or bladder dysfunction.

SEIZURES AND SYNCOPE
Seizures and syncope can be lethal from multiple perspectives. Injury to the patient and reoccurrence are real potential problems. Precautions for safety should be initiated in the ED as soon as possible. If the patient is discharged, warnings about driving and the operation of machinery are important for protection of the public in general. Such warnings should be indicated in some way on the patient’s chart.

TRANSIENT ISCHEMIC ATTACKS AND STROKE
Transient ischemic attacks and stroke are becoming larger issues. The American College of Emergency Physicians has gone on record as specifically stating that tissue-type plasminogen activator is not the standard of care for stroke. Lack of rapid evaluation of patients with a transient ischemic attack and the initial use of aspirin therapy have been the source of many ED lawsuits. Patients with transient ischemic attacks represent a high-risk group and require timely intervention.

TRAUMA
All EPs should know what they can and cannot do and should move quickly to ensure that the patient receives the actual help needed (Box 212.15). Administration of blood and treatment of shock are critical.

OBSTETRIC AND GYNECOLOGIC ISSUES
With regard to obstetric and gynecologic issues, it is important for the EP to realize that there may be two patients and not one (Box 212.16).

PEDIATRICS
The number of pediatric medical-legal cases in emergency medicine has actually decreased as rates of immunization and the various diseases that can be immunized against have increased. The keys to pediatrics are examination and early reexamination. Child abuse is a serious social problem in EDs. In general, you should never accuse anyone of abusing his or her child. You merely state that an investigative process is required because of the findings. It is important to emphasize that “they” make us do this type of investigation in these situations. Abuse and neglect are often difficult to separate in the ED, and such distinction needs to be made through social services. When in doubt, however, the child’s safety is paramount, and admitting a child for observation can certainly be a reasonable use of the hospital facility. Certain specific disease entities, such as sudden infant death syndrome, unusual burns, vaginal infections, certain types of fracture,
Missed ectopic pregnancies have decreased dramatically in the United States as a medical-legal problem since the widespread use of β-human chorionic gonadotropin testing and ultrasound scanning. A negative ultrasound does not rule out an ectopic pregnancy. Sudden loss of consciousness or shock in a young female patient should raise the possibility of a ruptured ectopic pregnancy until proved otherwise. Eclampsia is the second most common obstetric and gynecologic emergency. It can be present up to 2 weeks postpartum. In postpartum febrile female patients, ultrasound scans to check for retained products of conception and infection within the uterus are as important as checking the urine. Women who are 5 months into gestation and have sustained trauma to the abdomen should undergo a period of fetal monitoring in the labor and delivery department.

Fever in children younger than 36 months needs a probable source. Close follow-up is necessary. Splint musculoskeletal injuries for reevaluation in a week. Consider child abuse in children who visit the emergency department frequently and repeated toxic ingestions, should always be considered suggestive of child abuse until further information is obtained (Box 212.17).

**SUGGESTED READINGS**

improvements in ED patient care and technology. Revenue from patient care is obtained through two parallel billing structures: hospital billing and professional billing. This chapter focuses on professional billing.

CURRENT PROCEDURAL TERMINOLOGY CODES

Before publication of the Current Procedural Terminology (CPT) codes, third-party payers had their own idiosyncratic list of physician services and their respective codes, thus making consistent and reliable procedural billing extremely difficult. CPT coding was published by the American Medical Association (AMA) in 1966 in an attempt to standardize reimbursement for medical procedures. These codes are used to report physician services for claims processing and for local, regional, and national service utilization comparisons by the Centers for Medicare and Medicaid Services (CMS). CPT codes are reviewed annually by the AMA CPT Editorial Committee with input from various specialty physician organizations to account for new procedures and changes in reimbursement patterns.

A CPT code is a unique five-digit code that represents a service in contemporary medical practice that is being performed by physicians.1 Some common examples of emergency procedures and physician fees are listed in Table 213.1.

The emergency physician is legally accountable for claims based on the ED chart, including the potential for audits of electronic medical records by the Centers for Medicare and Medicaid Services and criminal penalties in cases of upcoding, such as assumption coding.

EVALUATION AND MANAGEMENT

The evaluation and management (E&M) codes are five CPT codes (see Table 213.1) that account for approximately 85% of all EP reimbursement. These five codes categorize the complexity of the encounter. Coders (and hence payers) rely on the documentation of historical information, physical

KEY POINTS

- The emergency department (ED) chart must be adequate to support billing and accurate to prevent claims of fraud against the emergency physician.
- Most reimbursement comes from the five levels of the evaluation and management codes and is dependent on a combination of historical and physical examination data, medical decision making, and diagnostic assignments.
- Billing for critical care requires more than 30 minutes of physician attention to a patient and obviates the level-specific evaluation and management charting requirements.
- Billing for observation requires separate documentation in the ED chart.
- The emergency physician is legally accountable for claims based on the ED chart, including the potential for audits of electronic medical records by the Centers for Medicare and Medicaid Services and criminal penalties in cases of upcoding, such as assumption coding.

ED, Emergency department.

Supplementing or confirming that this information has been reviewed by the attending physician.

Table 213.3A, Charting Requirements for Charts by Level, and Table 213.3B, Emergency Department Observation Codes and Descriptions, online at www.expertconsult.com

Certain statements commonly used in medical documentation deserve specific mention. The PMFShx should contain specific historical information obtained from the interview. Truncating the ROS with “all other systems negative” is adequate to meet documentation requirements for a level 5 visit; however, it should be used cautiously. When used indiscriminately in low-acuity patients, it may raise concern for upcoding and subject the EP to an audit. The designation “unable to obtain secondary to acuity or mental status” is appropriate for patients from whom no history can be obtained. EPs should document the specific clinical condition that prevents them from obtaining the history, as well as the specific source of the historical information obtained, such as nursing home records, family members, or electronic records.

MDM is the most complex and least clinically intuitive. MDM should capture in text the complexity of the decision-making process and reflect the intellectual workload of the EP. It should include at minimum two of the following three elements: the number of possible diagnoses or treatments, the tests or records reviewed, and the potential risk to the patient, including complications of treatment or possible morbidity or mortality (Table 213.4). When applicable, EPs should also list all major comorbid conditions affecting their decision making, consultations, and discussions with primary care providers.

In assigning diagnoses, EPs should list all diagnoses applicable to the patient’s current situation, including abnormal vital signs. For example, a hypotensive patient with diverticulitis and fever should have the diagnostic assignments of “hypotension,” “diverticulitis,” and “pyrexia.” Language that does not connote a specific diagnosis, such as “rule out,” “probable,” “motor vehicle accident,” “possible,” “chronic,” or “mild,” should be avoided. Including a breadth of diagnoses to paint a more thorough and accurate clinical picture of the clinical workload involved will maximize billing.

CRITICAL CARE

Critical care (E&M code 99291) is the E&M of an unstable, critically ill, or injured patient for which the EP’s constant cognitive attendance is required. Many intensive care unit admissions qualify for critical care billing because they involve “a critical illness or injury that acutely impairs one or more vital organ systems such that there is a high probability of imminent or life threatening deterioration in the patient’s condition.” Common clinical conditions that should prompt consideration of critical care include sepsis, abdominal aortic aneurysm, ruptured ectopic pregnancy, trauma, stroke, subarachnoid hemorrhage, atrial fibrillation with a rapid ventricular response, acute coronary syndrome, severe asthma, chronic obstructive pulmonary disease requiring bilevel positive airway pressure, diabetic ketoacidosis, and hyperkalemia. The first 30 minutes, up until 74 minutes of care, is billed with this code, after which additional increments of 30 minutes (code 99292) may be billed. The physician must be engaged examination, and medical decision making (MDM) to determine the complexity of the visit. The last digit of each CPT code is used to denote the “level” of service (Table 213.2). Services provided between the hours of 10 PM and 8 AM may be coded with an additional code, 99053. Each progressive level of service requires incrementally more documentation to support the level of coding. The EP must be sure to document an adequate history of the present illness (HPI), review of systems (ROS), and past medical, family, and social history (PMFShx) to support each level of the chart. This requirement increases substantially for level 4 and 5 charts (Tables 213.2A and 213.2B). The HPI should include a variety of descriptors of the chief complaint, including the relevant location, quality, severity, timing, context, and associated symptoms. The ROS and PMFShx can be recorded by ancillary staff (resident, nurse practitioner, and others) or on a form completed by the patient but must have a notation

in work directly related to the individual patient’s care. Because of the implied severity of the patient’s condition, none of the history or physical examination requirements apply to qualify for critical care billing. Certain procedures associated with critically ill patients may be “bundled” with the critical care payment and thus are not billable separately. Such procedures include arterial blood gas, electrocardiogram (ECG), chest radiograph, and pulse oximetry interpretation; gastric intubation; temporary transvenous pacing; ventilator management; vascular access; cardiopulmonary resuscitation (CPR); and defibrillation.

**BILLING COMPLIANCE**

Accuracy is essential to avoid issues of fraud and abuse. All EPs are individually responsible and accountable for correct processing of the claims associated with their charts. It is incumbent on EPs to document the visit accurately without underrepresenting or overrepresenting the encounter’s complexity. Using electronic macros with identical documentation of HPI and MDM across different patient encounters can be a red flag to billing auditors. Cutting and pasting text verbatim is strongly discouraged by the CMS. Ancillary providers and scribes may be used to document information on the chart but must have their own electronic signature.

Recovery Audit Contractors (RACs) are auditing groups hired by the CMS to review the documentation supporting claims to detect and correct payments that are not supported by adequate documentation of a clinical encounter. RACs review claims on a postpayment basis by using two types of review, automated (no medical record needed) or complex (complete medical record required). A RAC employs a staff consisting of nurses, therapists, certified coders,
and a physician to review reimbursements with the goals of lowering inappropriate reimbursement rates by the CMS, providing public accountability of health care expenditures, and providing feedback to EPs submitting claims that do not comply with Medicare reimbursement rules.

Documentation is perhaps most important when it comes to protecting EPs from claims of fraud in providing care. Procedures or services that are billed for and not documented, regardless of whether they occurred, are considered fraudulent and are subject to criminal penalties. Assumption coding is defined as billing at a higher level than what the chart supports. For example, a patient with chest pain and changes on the ECG who is admitted on intravenous heparin qualifies for a level 5 encounter. However, if the EP seeing this patient documents only a four-element HPI, 5 physical examination points, moderate-complexity MDM, and “rule out myocardial infarction” as the diagnosis, the evidence provided by this chart is inadequate to support billing above level 4. If this chart were reviewed, the EP would be liable for filing a fraudulent claim. To protect physicians from such pitfalls, physician groups or hospitals should have compliance review committees in place to review charts in a systematic fashion to ensure that EP documentation and chart coding are appropriate and consistent for the patient services rendered.⁶

PROCEDURAL BILLING

Wound care and closure are of particular relevance to EPs. Adhesive closure of lacerations is billed at a lower “G” code RVU rate unless deep absorbable sutures are also placed, which allows standard laceration billing (see Table 213.1). Wounds requiring decontamination or débridement may be considered intermediate-complexity laceration repairs even if only a single-layer closure is required. Burn care can be billed for burns requiring the application of topical ointment and dressing. CPR may be billed separately but not contemporaneously with critical care time. Critical care billing would start only after completion of the course of CPR. Intubation currently continues to be a single CPT code and does not account for more advanced or resource-intensive methods such as fiberoptic modalities.

The CPT allows billing for interpretation of findings on the ECG, radiograph, and ultrasound if such interpretation is adequately documented in the record. An ECG interpreted as “normal” would not be billable, whereas an interpretation of “sinus rhythm, no ST changes, no ischemia, unchanged compared with prior ECG” would qualify. The EP should note when these are interpreted independently.

OBSERVATION CARE

Observation care billing codes exist for E&M services provided to patients designated or admitted to “observation status” in an ED or ED observation unit. These services are separate from the ED visit and hence require separate documentation, including an admission order, admission note referencing the ED record, progress notes, a discharge note, and a discharge order on release of the patient. Observation charts may be billed at levels 1 to 3 based on the complexity of the history, physical examination, and MDM, similar to ED chart billing (see Table 213.3B). Physician extenders such as nurse practitioners (NPs) and physician assistants (PAs) may be used to staff an observation unit. Although PAs require direct attending oversight, NPs may operate independently; however, Medicare reimburses independent NP services at only 85% of the physician rate. To qualify for full reimbursement as a “shared visit,” the EP must document the history, physical examination, and MDM and make note of review of PA or NP documentation.

HOSPITAL BILLING AND CAPTURABLE REVENUE

In addition to the physician services provided to patients during their visit, hospitals also generate bills covering the use of their physical plant and materials. Hospital billing is accomplished through Ambulatory Payment Classifications (APCs), which are Medicare groupings of more than 5800 CPT codes into approximately 540 categories. APCs are flat payments for taking care of patients with a particular diagnosis regardless of the cost incurred by the hospital. For example, a hospital involved in the treatment of a patient with pneumonia receives a flat payment regardless of the antibiotic given and the duration of the patient’s stay in the hospital. Both nurse and physician documentation contributes to the number of APCs that may be billed on a given patient’s stay based on how many diagnoses and services are documented.

The payer mix of an ED is the variety of insurance coverage for a patient population that determines the cash flow for a physician group. After the ED chart has been coded and billed to an insurer, the return on the dollar amount, or capturable billable revenue, is approximately 40%. Payment is sent out approximately 40 to 100 days after the bill is submitted, thus causing a significant delay in reimbursement for the department or physician group. This cycle time makes timely completion of ED charts essential to ensuring cash flow. Metrics such as chart completion by the provider, distribution of E&M visits per provider, RVUs per provider, and charges or collections per payor over time are critical to ensure the financial health of a department.
**REFERENCES**

CPR holds a unique position in medicine and society. It is the only medical intervention that the patient must take steps to refuse in advance because of presumed consent, even if the clinician does not believe that it is beneficial or medically warranted. Ethical dilemmas surrounding the initiation, continuation, and cessation of resuscitation are common.

Patient autonomy, nonmaleficence (doing no harm), beneficence (promoting good or well-being), and justice (being fair) are the guiding principles of medical ethics. For a patient to make autonomous decisions about resuscitation preferences, the patient (or designated medical decision maker) should be given the best information available to weigh his or her medical care options. The Jonsen model for ethical decision making suggests that the following four “ethical quadrants” be weighed: medical indications, patient preferences, quality of life, and contextual features.

Despite much debate and discussion, medicine and society have not been able to agree on a common and accepted definition of the term medical futility. One suggested paradigm of medical futility characterizes a medical intervention as futile when its goal will not probably be achieved. Although one common medical goal of clinicians who perform CPR after cardiac arrest is return of spontaneous circulation, the patient, surrogate, and clinician may have other equally important goals, including neurologic outcome and quality of life after resuscitation. Timely discussion between the clinician and the patient or his or her designated decision maker regarding the goals of care is paramount to ensure quality end-of-life care.

Noninitiation of CPR is increasingly being described as “allow natural death.” It is of utmost importance for clinicians to understand that before CPR, a host of interventions may be used to extend life but, in the event of death, the option may be to not attempt CPR. For example, research suggests that in cancer patients for whom all aggressive interventions (antibiotics, fluids, pressors, airway support) have been tried, in the event of death the success of CPR in achieving survival to discharge is zero.

On the road to eventual death, patients may have a constellation of physical, psychologic, and emotional symptoms that can be treated. The majority of patients who are critically ill are not in active cardiac arrest at initial encounter but are at high risk for it. Emergency physicians (EPs) most often care for these patients at high risk for cardiac arrest and may find themselves ethically driven to discuss with patients and families the appropriateness of resuscitative efforts to reverse death in the event of cardiopulmonary arrest.
### EPIDEMIOLOGY

Out-of-hospital cardiac arrest (OHCA) has an incidence of 52.1 per 100,000 population, which makes it the third leading cause of death in North America. The survival rate of patients experiencing OHCA after treatment by emergency medical services is approximately 8%, but it varies widely among regions. For patients who suffer in-hospital pulseless cardiac arrest, survival to hospital discharge depends widely on the characteristics of the arrest and patient comorbid conditions (Table 214.1). Research suggests that when talking with patients, physicians can describe the overall likelihood of survival after cardiac arrest include cancer, dementia, sepsis, cardiac disease, elevated serum creatinine, and African American race. Despite these well-publicized numbers in the medical literature, EPs should be aware that patients and their families may have very different expectations of resuscitative efforts after cardiac arrest. Popular U.S. television programs, for example, incorrectly suggest that the immediate survival rate after cardiac arrest approaches 75%, with 67% of patients being portrayed as surviving to hospital discharge.

### PATHOPHYSIOLOGY

Cardiac arrest is the sudden, abrupt loss of heart function. The most common underlying reason for patients to die suddenly after cardiac arrest is coronary heart disease. Most cardiac arrests that lead to sudden death occur as a result of arrhythmias such as ventricular tachycardia or ventricular fibrillation. A patient's chances of survival after cardiac arrest are reduced by 7% to 10% with every minute that passes without CPR and defibrillation. Few attempts at resuscitation succeed after 10 minutes.

### PRESENTING SIGNS AND SYMPTOMS

One classic scenario illustrating many of the ethical dilemmas surrounding resuscitation is a patient who arrives at the ED critically ill with possible impending cardiac arrest or with signs of active dying (Table 214.2). Decisions must be made quickly regarding which life-extending measures will be used while also simultaneously ensuring relief of patient distress. If a patient is likely to deteriorate rapidly or shows signs of imminent death, a discussion regarding resuscitation should be initiated with the patient or the appropriate surrogate. The EP should make a clinical assessment that includes evaluation of the goals of care, determination of the presence or absence of an advance directive, and a recommendation regarding the utility of CPR to meet the patient's goals of care. Table 214.2 lists the signs of active dying in the setting of a chronic progressive incurable illness, such as late-stage cancer, dementia, or failure to thrive.

### DIFFERENTIAL DIAGNOSIS AND MEDICAL DECISION MAKING

Before discussions with patients and families about critical illness, the EP may be able to initiate several easy medical
interventions to provide important and valued information for patients and their families to inform the medical recommendation. Bedside glucose testing and pulse oxygen saturation measurements, for example, may be sought. Rapid measurement of serum electrolytes (potassium in particular) may yield a quick overview of the patient’s renal or acid-base status. Bedside ultrasonography is a minimally invasive way to diagnose potentially lethal catastrophes such as pericardial tamponade and rupture of an abdominal aortic aneurysm. Bedside electrocardiography may detect myocardial infarction. Good clinical information can help guide decision making.

**TREATMENT**

Temporizing measures that might “buy time” for discussion of the medical and ethical grounds for resuscitation, for examination of the medical record, or for contact of a provider more familiar with the patient should be considered on a case-by-case basis.

**RED FLAGS**

Emergency physicians should advise patients and surrogates on the utility of resuscitation based on best available evidence to achieve a patient-centered meaningful outcome.

Patients who have do-not-resuscitate orders may desire life-sustaining treatments up to and until cardiac arrest.

**FOLLOW-UP, NEXT STEPS IN CARE, AND PATIENT EDUCATION**

The medical condition and comorbid conditions of individual patients make each person’s survival rate highly variable. Discharge survival rates and function in patients with chronic, progressive terminal illnesses such as end-stage cancer, heart failure, and pulmonary and neurologic diseases, for example, tend to be extremely poor. Increasingly, language such as “allow natural death” and “do not resuscitate” suggests that no attempt be made to initiate CPR in the event of physiologic death. However, other measures—oxygen, fluids, nutrition, pain control—may still be initiated to support patient comfort.

Patients or their medical decision makers who choose to forgo measures such as CPR may also, but not necessarily, choose a more global comfort approach to their end-of-life care. The EP should be able to provide palliative measures and support this comfort care (Table 214.3). It is important to recognize, however, that these patients may still need

<table>

</tr>
</tbody>
</table>
intensive in-hospital care. In some cases, transfer of a patient from the emergency department to a hospice may be possible. More often, patients are admitted to the hospital and may require temporary intensive care to assess the goals of care and adequately achieve comfort. For a patient who is undergoing advanced life support measures, such as invasive ventilation and cardioactive drugs, a time-limited trial may help the patient and his or her family feel more comfortable delineating the goals of care.

Emergency Medical Services and Disaster Medicine

Jennifer Avegno and Jeffrey M. Elder

INTRODUCTION AND HISTORY

An emergency medical services (EMS) system can be defined as “a coordinated arrangement of resources (including personnel, equipment, and facilities) organized to respond to medical emergencies, regardless of the cause.” Modern EMS systems in the United States have their origins largely in battlefield medicine. Indeed, it was a surgeon in the Napoleonic military campaign who pioneered the concept of rapid response to injured soldiers in the field of combat. Baron Larrey, the “father of modern prehospital care,” developed a systematic approach to combat trauma in which ambulances transported wounded soldiers from the battlefield to organized medical stations. In the American Civil War, ambulances were placed under structured medical direction. Successive advances in technology and EMS organization in later wars resulted in significantly decreased mortality rates for battle combatants who were transported to field hospitals.

Although civilian “rescue societies” and ambulance services existed from the mid-1800s, the most significant non-military advancement in EMS occurred in the 1950s with the establishment of life support training programs through the Chicago Fire Department. From this effort the basis for the now widely accepted emergency medical technician (EMT) and paramedic training programs were formed. By the 1960s, some regions had nascent ambulance systems with paramedics trained in advanced life support (ALS) techniques, although others developed a separate system of “heartmobiles” with physicians on board to provide care only for cardiac emergencies.

The need for sophisticated, coordinated EMS systems was brought to the national spotlight in 1966 with publication of the National Academy of Sciences paper titled “Accidental Death and Disability: The Neglected Disease of Modern Society.” This paper noted that few people were trained in advanced resuscitation, no widely accepted standards had been established for training ambulance personnel, and communication systems and supplies were lacking. This report spurred a national, organized effort to increase awareness of traumatic disease and the need for development of a comprehensive EMS system. Congress responded with the National Highway Safety Act of 1966 and the EMS Systems Act of 1973, which authorized federal grants to state, local, and regional governments for the development of EMS systems within a specified “systems approach” framework. In 1981, however, guaranteed federal funding for EMS was replaced with state block grants and increased financial insecurity. Currently, nearly 1 million people are certified in some form as emergency response personnel, and nearly 20 million patients are treated in the EMS system annually, but heterogeneity in system design, scope, and certification requirements persists.

EMS SYSTEM DESIGN

EMS systems are, arguably, some of the most complex organizational entities in modern society. They include representatives from municipalities of every size, law enforcement, fire and safety, health care, transportation services, and community groups. Federal governing bodies define the necessary components of EMS systems but do not directly oversee organization or management. Coordination between agencies is essential but often difficult to achieve. Ideally, EMS system design is centered around the particular needs of the community it serves, with one standard characteristic: emergency medical personnel act as on-scene “physician
surrogates” to provide appropriate life support techniques. Common models categorize different systems in terms of control by the public or private agencies, rural or urban communities, and single-tiered or multitiered systems.

PUBLIC AND PRIVATE AGENCIES
Public EMS systems are often part of the local fire department organization and are more common in large urban counties or cities. This structure developed in the early days of EMS systems as a result of logistic concerns: fire stations were located at tactical points throughout communities and had experience in emergency response. Firefighters could be trained in basic life support (BLS) techniques and thus could function as both fire/safety and emergency medical personnel. Alternatively, public EMS systems may be municipal “third-service” entities that do not fall directly under fire or police organization but may be interconnected with these agencies under a larger public safety institutional structure. Public EMS systems are generally funded through a combination of local taxes, user fees, and patient insurance.

Private EMS systems may be hospital based, locally owned, or subsidiaries of a large national corporation. Depending on the community, these organizations may provide interfacility transfers, as well as respond to local 911 calls. In some areas, private firms constitute the designated first or second responder for all calls and also provide routine transport of nonemergency patients (e.g., scheduled patient trips to dialysis or rehabilitation facilities). Financing generally depends on individual patient insurance and user fees, with occasional government subsidies. Hospital-based systems may be based out of one hospital or a larger hospital organization. If they are under the control of a state or county-run hospital, they may operate under public authority in concert with other safety agencies.

Public-private hybrids are quite common. A local government may contract with one or both types of EMS systems for fulfillment of specified emergency services in a particular region. For example, fire department personnel may be the designated first responders for all 911 calls, but a private or public ambulance may transport all patients from the scene to the hospital. Financing may involve direct patient billing, reimbursement from local government, or a designated fee for services.

RURAL AND URBAN EMS SYSTEMS
The design of and challenges faced by EMS systems are often significantly different between rural and urban areas. In general, rural systems developed later than urban ones and are more likely to be staffed with unpaid volunteers. These volunteer-based organizations may be public or private and are generally nonprofit entities. Volunteers are usually citizens with outside employment who offer their services on an unpaid basis for emergency response, training, and community education. Funding is largely through taxes and municipal support, although private donations and fund-raising are often necessary. Volunteer EMS systems face many challenges that are representative of rural systems as a whole, namely, high cost to cover large geographic areas with few citizens, high response times, lower levels of training, and relatively low patient volumes. Urban EMS systems have their own distinct set of difficulties, among them high patient volumes, traffic congestion, and limited resources.

Evidence suggests that rural emergency morbidity and mortality is significantly greater than that for comparable urban patients. Reasons for this difference include longer response and scene times, lower patient volumes, and less overall training for first responders. Technologic advances such as “E911” (enhanced 911) show some promise in significantly reducing emergency responders’ transport time to the scene. Adapting specific on-scene protocols and increasing access to high-quality medical care (prehospital and in-hospital) in rural areas have also been suggested as possibilities to decrease the gap in rural-urban adverse outcomes.

SINGLE-TIERED AND MULTITIERED SYSTEMS
EMS systems are further divided by hierarchic types. In single-tiered systems, all dispatched calls are serviced by a single level of first responder and vehicle. In contrast, multitiered systems have variable types and levels of personnel, equipment, and vehicles available for response. A typical multitiered model includes both “first responders”—police or fire department personnel who are strategically geographically located throughout the area—and a second-tier response of more skilled paramedics and EMS personnel. First responders generally have limited training in BLS techniques such as lifesaving airway maneuvers, hemorrhage control efforts, and cardiopulmonary resuscitation (CPR). The second-tier response can usually provide advanced emergency techniques and transport to the hospital.

In addition to the basic first-response, advanced transport system just described, other multitiered EMS designs may be used. Examples include police or fire first response with private ambulance transport, ground first response with air transport, BLS transport with an ALS intercept vehicle as needed, and separate ALS response and transport vehicles. All systems are designed, in theory, to minimize EMS response, scene, and transport time while providing the highest possible quality of patient care.

EMS SYSTEM ORGANIZATION, TRAINING, AND TRANSPORT TYPES

DISPATCH AND MEDICAL CONTROL
In the United States, 99% of the population has access to 911 for emergency calls. Most dispatch centers use E911, a system whereby the caller’s location is shown on the dispatch operator’s screen. Formal training for 911 dispatch personnel exists, and national guidelines that advocate for certification standards have been established. There is a trend toward consolidation of all emergency calls into one 911 center, where dispatchers take calls and then directly relay information to the appropriate EMS or public safety agency. Dispatch actions and instructions may be shaped by established guidelines that allow adaptation to the situation at hand or by more rigid protocols that detail a specific plan of action. Some agencies may rely on computerized algorithms to assist dispatch; a controlled trial of British nonurgent emergency calls found that using a computerized decision tool plus either nurse or paramedic input resulted in more than half the calls triaged as not needing an emergency ambulance. However, only 20% of these callers chose to cancel the ambulance, and this group had similar hospital admission rates as those triaged as needing emergency transport.
EMS systems rely heavily on both online (direct) and off-line (indirect) medical control. Physician involvement in EMS medical control developed as physicians spent less time directly in the field and paramedics increased their training and ability to act as physician surrogates. Every EMS system is headed by a medical director, a physician with or without specialty training who has direct authority over operation of the system, performance of emergency personnel, and patient care. Standardized guidelines and requirements for EMS medical direction have been published by the American College of Emergency Physicians (ACEP) (19,20).

Online medical direction involves direct communication about patient care between on-scene emergency responders and the EMS medical director or a designated representative. Depending on the region, online medical control may be provided by a single centralized facility (base station) such that all calls requiring medical control—regardless of their destination—are handled by one institution. In other areas, each receiving hospital may have its own medical control and handle calls specifically directed toward that facility. The personnel responsible for direct medical control must be knowledgeable about specific protocols or regional system capabilities to provide accurate information about patient care in the field and appropriate transport.

The evidence basis for improved patient outcomes with online medical control is mixed. It has been shown to significantly increase on-scene time, and orders given rarely deviate from existing protocols. (21-23) However, there is some evidence that online medical direction may decrease the use of inappropriate resources while preserving outcomes in some patients. (24) The greatest benefits of online direction may be in resolving difficult ethical or medicolegal situations on scene and in notifying receiving hospitals of incoming critical patients so that resources can be assembled and are ready before arrival of the patient.

Off-line medical direction refers to written protocols that guide common patient interactions, as well as continuing education and quality assurance initiatives. EMS systems have specific protocols for commonly encountered situations that, ideally, should improve patient outcomes and reduce time at the scene. Protocols should be developed on the basis of patient history, mechanism of injury, physiologic characteristics, local hospital capability, and transport times. Medical directors should be active in developing and implementing protocols, as well as in training responders in their application and quality evaluation of patient records. (25) Research indicates that use of well-developed standing protocols significantly reduces on-scene time and decreases inappropriate treatment in the field. (26) Furthermore, diagnostic accuracy plus agreement with physician assessment of patients is generally high. (27)

EMS RESPONDER PERSONNEL

Before the National Academy of Sciences paper on trauma in the 1960s, few standardized training programs existed for EMS personnel. Subsequent creation of the Department of Transportation resulted in a formalized 70-hour curriculum for basic EMT certification. Passage of the EMS Systems Act of 1973 provided millions of dollars for EMS training, equipment, and research and identified basic elements that must be included in all EMS systems (Fig. 215.1). (28) However, until recently, heterogeneity of regional systems persisted such that a 1996 survey identified more than 40 different types of EMS personnel certification across the country. (29)

In general, EMS personnel are categorized into four skill levels: first responders, EMT-basic (EMT-B), EMT-intermediate (EMT-I), and EMT-paramedic (EMT-P). First responders undergo roughly 50 hours of training in basic first aid, CPR, uncomplicated obstetric delivery, simple wound and fracture care, and use of automated external defibrillators (AEDs). EMT-B personnel receive first-responder training plus an additional 50 to 60 hours of education in triage, extrication, transfer, oxygen and self-medication assistance, and possibly advanced airway techniques. Most U.S. ambulances are staffed with at least one EMT-B. EMT-I requirements often vary by state but generally include invrenous access and monitoring and possibly advanced airway and life support measures. EMT-Ps undergo EMT-B training plus at least 250 to 500 additional hours of education, including in-hospital experience. They are skilled in advanced airway and life support techniques, vascular access, monitoring, and administration of medication per local protocols.

Recognition of the wide regional variation in training standards and skill levels led to development of the National Highway Traffic Safety Administration National EMS Scope of Practice Model in 2005. This consensus document promotes national standardization in training and education to improve consistency within and among agencies, increase public understanding of EMS roles, and move toward a coordinated national EMS system. (30) The model advocates four separate and sequential levels of certification—emergency medical responder, EMT, advanced EMT, and paramedic—and clearly defines minimum educational levels and skill sets for each. Most states have already implemented or are in the process of testing these national guidelines for local use.

There is some evidence basis for the current multilevel EMS personnel system. Early EMS research found a significant reduction in mortality from cardiac arrest with the use of paramedic responder crews versus EMT-Bs. (30,31) Outcomes in trauma have also been shown to improve significantly when ALS-capable ambulances are on scene as compared with BLS personnel. (32,33) However, other studies evaluating paramedic-and non-paramedic-containing crews found mixed results. In general, on-scene time is significantly longer for crews in which one or all of the responders are paramedics. (34,35) Paramedic crews had higher skill levels and provided more on-scene interventions, but some authors suggest that their presence on every ambulance may not be warranted. (36)

EMS VEHICLES, EQUIPMENT, AND TYPES OF TRANSPORT

Equipment available on emergency transport vehicles varies by both type of vehicle and the skill level of responder personnel on board. Joint guidelines developed by the ACEP and the American College of Surgeons detail the minimum necessary supplies for appropriate patient care. (37) Items needed for basic-level interventions include ventilation and airway equipment, monitors and defibrillators, immobilization devices and bandages, mobile communication devices, obstetric and pediatric specialty equipment, and infection control and injury prevention measures. Ambulances with advanced life support
Criteria for air transport can vary widely by EMS system, and overtriaging is common. The National Association of EMS Physicians has published guidelines regarding the use of various methods of air transport, as well as which patients are most likely to benefit from its use. In general, helicopters are best used for transport involving a shorter distance (less than 100 miles) but are subject to weather concerns. Fixed-wing aircraft are preferable for distances greater than 100 miles and are less dependent on inclement weather, but they must land at airports (thereby prolonging transport time). Severely injured trauma patients at some distance from a regional trauma center are most likely to benefit from air transport or transfer; critically ill non-trauma, cardiac, pediatric, and possibly obstetric patients may also have improved outcomes in selected situations.

The safety of both patients and medical staff is a prominent issue in air medical transport. As the number of flights has increased in recent years, so has the number of aircraft accidents. Between 2002 and 2005, 55 crashes occurred and resulted in 54 fatalities; the incidence of aircraft accidents per number of flights increased as well. Patient safety in flight is also of concern; an estimated 5% of patients suffer a “critical event” (decompensation or deterioration) during transport. Factors such as weather, time of the day, terrain, communication difficulties, and medical crew training have been found to be associated with adverse events, but more study is needed to improve air transport safety.
CURRENT CONTROVERSIES IN EMS

Research on the influence of EMS systems on patient outcome is a growing field. Ideally, well-designed studies should investigate the impact of EMS system design, training, personnel, and operation on community needs and patient outcomes. Most studies to date have focused on several broad topics: cardiovascular emergencies, prehospital interventions, trauma, and response times.

CARDIOVASCULAR EMERGENCIES

Some of the earliest organized EMS research focused on cardiac arrest and early CPR and defibrillation. A 20-year review of EMS systems in 29 cities found that systems with a single emergency responder were associated with lower rates of survival of patients in cardiac arrest than were two-responder (EMT and paramedic) systems, largely because of early CPR in the latter. Time to defibrillation has consistently been found to improve outcomes after cardiac arrest. A 25-year retrospective review of cardiac arrest with EMS intervention found that survival rates remained unchanged; however, the authors suggested that improvements in EMS delivery, such as dispatcher-assisted bystander CPR and early defibrillation, balanced the adverse temporal trends that would otherwise have increased mortality rates. New life support guidelines emphasize the role of EMS dispatch in instructing hands-only CPR to bystanders and widespread use of AEDs, both of which are considered to be an important adjunct to trained EMS response.

PREHOSPITAL RESUSCITATIVE INTERVENTIONS

Advanced resuscitative techniques, such as endotracheal intubation and intravenous fluid administration, are frequently performed by skilled paramedics on critically ill patients. Common thinking has been that earlier intervention should improve outcomes; however, solid evidence supporting prehospital intubation is lacking. Although studies are most frequently observational, the literature available suggests that EMS intubation does not improve morbidity and mortality and may in some cases worsen patient outcomes. Similarly, a recent large multicenter study found that prehospital intravenous fluid administration was associated with increased mortality in nearly all subsets of trauma patients, particularly those with penetrating trauma, hypotension, and severe head injury. This evidence indicates that a “less is more” or “scoop and run” approach to EMS transport may be safer for patients.

TRAUMA

Much research on EMS response to trauma focuses on response times and the perceived benefit of “regionalization” of trauma care—that is, linking prehospital systems with participating hospitals, public health agencies, and other care providers within a certain region to achieve optimal system efficiency and outcomes. Regional systems generally have specific protocols governing EMS responder actions and transport to specialized trauma centers when appropriate. Even though patients transported directly to designated trauma centers in lieu of the closest facility have more critical injuries, mortality generally remains low, largely because of decreased prehospital time until direct transfer to the specialty hospital. Despite the advantages of regionalization, the effect of EMS transport to a trauma center may not always be significant. Some evidence suggests that critically ill patients transported to a trauma center by EMS arrive at the hospital significantly faster than did patients in private vehicles but have no significant improvement in mortality rates, complications, or length of stay.

RESPONSE TIME

EMS response time is often used as a benchmark of overall system performance, with accepted standards of 4 minutes for BLS and 8 minutes for ALS arrival. Specifically, national guidelines recommend medical intervention within 4 to 6 minutes of EMS activation for patients in cardiac or respiratory arrest, although such intervention may include dispatcher-assisted bystander CPR or AED use. Studies of set response time criteria have shown mixed results. Retrospective and post hoc analyses of urban EMS transport show a possible survival benefit for patients transported to hospitals in 4 minutes or less, although the advantage was not significant for those not in cardiac arrest. E911 systems—in which caller location is available instantly—can decrease response times because they help plan more direct routes to the scene and reduce the likelihood of ambulance crews becoming lost. Furthermore, response times should be targeted to specific regional needs and may be maximized by a strong community-wide first-responder presence, strategic placement of ambulances based on historical call data, mobile mapping or global positioning systems, and adequate fleet maintenance.

From their earliest beginnings as purely military organizations to the complex heterogeneous models in place today, EMS systems have evolved into critical providers of health care and a critical component of modern emergency medicine. In 2010, EMS was approved by the American Board of Medical Specialties as the sixth subspecialty of emergency medicine, with development of standard examination and certification procedures underway. This further solidifies EMS as a distinct clinical subspecialty involving the prehospital care of sick and injured patients, regardless of specific local or regional system design.

DISASTER MEDICINE

INTRODUCTION AND HISTORY

Disaster medicine can be defined as “a sudden and extraordinary misfortune that overwhelms the immediate ability to manage or compensate.” Increasing attention has been focused on this nascent medical specialty in recent years with such high-profile disasters as the September 11, 2001, terrorist attacks and severe natural disasters such as hurricanes, earthquakes, and tsunamis. With each successive disaster and its medical and public health response, more is learned and planning can be refined for the next event.

Although the existence of apathy toward disaster planning (and resource allocation toward this end) is well documented, major and minor disasters occur with regular and increasing frequency. In the past hundred years, millions of lives have been lost internationally from natural disasters. In 2005, Hurricane Katrina—related flooding was responsible for more than 1500 fatalities along the U.S. Gulf Coast. Worldwide, flooding of the Yangtze River in China caused 3 million
casualties in 1931, deaths from the Indian Ocean tsunami in 2004 approached 300,000, and the devastating 2010 Haiti earthquake killed more than 230,000 and displaced up to an additional 2 million. Over the years, earthquakes, landslides, volcano eruptions, and massive fires have resulted in staggering economic losses, population displacement, disease, and death. Research suggests that losses from natural disasters are probably only going to rise because of growing population density (particularly in high-risk areas) and increased hazards as a result of rapidly expanding technology (i.e., transportation of more dangerous materials, fire threats in high-rise buildings, vulnerable financial and economic infrastructure).62

Despite the clear threats from natural disasters, much of the focus of disaster medicine in recent years has been placed on intentional, man-made events—namely, terrorism and mass casualty incidents. Even before the devastating terrorist attacks on New York City in 2001, researchers predicted that the probability of exactly such an event was extremely high.64 Despite performing a mass casualty drill just 3 days before September 11, none of the existing protocols or triage systems proved adequate for the resulting event.65 Subsequent creation of the Department of Homeland Security (DHS) has provided federal agency support for and focus on expanded research into and development of all aspects of disaster planning for man-made incidents.

DEFINITIONS AND CLASSIFICATIONS
In general, disasters are classified by their relationship to the hospital setting, inciting event (natural or man-made), and the anticipated necessary response. Internal events occur solely within a particular hospital or medical center (e.g., power outage, building collapse), whereas external events involve some part of the larger community. This system is most useful in preparing the facility to either receive patients from outside or deal with internal problems; however, many disasters have both internal and external effects, and such a narrow classification scheme is not easily applicable to a variety of situations. In terms of anticipated response, most disasters are classified into one of three categories. Level I disasters are those in which local emergency response teams and organizations are adequate to manage the event alone. Level II incidents require a regional approach and mutual aid from surrounding areas. Level III events overwhelm local and regional efforts and require state or federal support.65

DISASTER PLANNING
Although The Joint Commission (TJC) requires all health care facilities to conduct two disaster drills per year, disaster planning is rarely emphasized or sufficient. Many factors contribute to the inadequacy of most hospital or regional disaster plans, namely, the unexpected and sudden nature of most events (thus making prospective evaluation impossible), poor record keeping, faulty assumptions on which significant parts of the plan are based, and failure of communication and command structures.66 For disaster plans to be effective, they must be based on valid assumptions of what may occur in a variety of event settings. Furthermore, the planning process must include all systems and organizations that will be affected by the disaster and have a role in its aftermath, and all parties must have a working knowledge of the plan, the chain of command, and their role in it.62

Critical to the development of an appropriate plan is a hazards analysis of particular events to which a hospital or region is most susceptible. In this manner, organizations can plan effectively for the types of disasters that they are most likely to experience. A standard tool for evaluating hospitals’ disaster plans is available through the Agency for Healthcare Research and Quality.67 Frequent rehearsals of disaster plans are of utmost importance. A written plan is useless unless it is thoroughly understood and practiced by all parties involved.62 Rehearsals should be varied and include single-agency drills, tabletop exercises with participating community organizations, functional experiences with state and local emergency operations centers, and a full-scale interagency real-time drill. The latter should be as realistic as possible, with mock patients, evolving scenarios, and full community-wide participation. Equally important to any disaster plan is the “afteraction”—discussion of the drill or real-life event with a focus on identification and rectification of problems and appropriate refinement of the plan.68

A good disaster plan should cover both internal agency and external community needs and focus on all phases of the inciting event: prodrome/mitigation, impact, rescue, and recovery.2,63 Interhospital plans should involve all departments responsible for patient care and infrastructure and detail clear policies related to the chain of command and physical control centers, communication and public relations, record keeping, personnel needs, and equipment and resource supply. External planning should involve all local agencies responsible for protection and care of citizens. The Incident Command Structure (ICS) provides a means to delineate a clear chain of command and management structure during critical events. Developed after a series of devastating California wildfires in the 1970s, this model provides for an overall incident commander of any disaster event who oversees predesignated public responsibilities, logistics, finance, supply, and organizational section chiefs. Each section has a variety of personnel with specific duties and areas of focus who report to the chiefs at regular intervals. The ICS is frequently revised and is designed to be flexible, predictable, and accountable, with improved documentation, common language, and cost efficiency.69

DISASTER RESPONSE
Response to a catastrophic event requires rapid mobilization and efficient use of available resources. Clear and defined roles should be established for prehospital providers, health care facilities, and all levels of governmental agencies involved in public safety and welfare. The usual standard of medical care may not be possible or desirable in the acute postdisaster period, and alterations in practice will probably be necessary, within accepted boundaries.70

Prehospital Disaster Response and Triage
Though fully capable of responding to individual emergency calls, most local EMS systems are often not able to respond adequately to a widespread or overwhelming event.71 The concept ofprehospital triage, used routinely by EMS, is of utmost importance in managing disasters. Unlike routine triage—where the aim is to identify those few critically ill patients who require immediate, aggressive resource utilization—disaster triage attempts to “do the most good for the most people” and often requires that seriously injured
victims receive little to no immediate care. Disaster triage models attempt to rapidly identify individuals who will benefit most from immediate stabilization with the least amount of available resources.

The simplest method of triage assigns each patient a color-coded tag with frequent opportunities for reassessment (Fig. 215.2). Green tags are given to patients who require minor, nonimmediate medical intervention. Yellow tags indicate potentially serious injuries, but ones that are relatively stable and can wait a short period. Red tags designate patients who have life-threatening, but potentially treatable injuries that require immediate medical care. Black tags signify dead or critically ill patients who will not survive without significant use of resources and time unavailable under disaster conditions. For example, an apneic victim of a large-scale blast injury with significant head and abdominal injuries may be tagged “black” because the immediate resuscitative and stabilization needs of the victim would require an inordinate use of personnel and equipment given the number of victims and likelihood of a meaningful outcome.

Tag systems are combined with triage models to provide specific algorithms for classification of patients. Widely used in the United States, the START (Simple Triage and Rapid Assessment) system triages mass casualty patients by several simple variables: breathing, ambulation, radial pulse, and ability to follow commands (Fig. 215.3). Patients are categorized as “green” if they are initially ambulatory with minor injuries. “Yellow” victims are those who may be unable to walk but are breathing with respiratory rates lower than 30 breaths/min, are well perfused (capillary refill longer than 2 seconds), and can follow simple commands. Patients with respiratory rates higher than 30 (with or without airway positioning), delayed capillary refill, or inability to follow simple commands are tagged as “red,” and the need for immediate lifesaving attention is assessed. Apneic patients are tagged as “black,” and no further interventions are performed. Refinement of this model has led to specific, but still simple modifications for pediatric patients.72

The SAVE (Secondary Assessment of Victim Endpoint) model was developed as an adjunct to the START system. After primary assessment with START, secondary triage is performed with SAVE to assess the following: prognosis if only minimal treatment is performed and prognosis with just the available resources on site or at the disaster medical aid center. Patients are sent to a treatment area only if treatment will reduce morbidity or mortality within the delayed time to definitive care without consuming a disproportionate amount of resources.73 The SAVE protocol provides specific guidelines based on age, injury location (head, extremity, spine, chest, and abdomen), and type of injury (burns, crush injuries, blunt or penetrating trauma) and suggests treatment priorities in order of likelihood of success (Box 215.1).

The START system has been shown to have high sensitivity, be quick to administer, and easily be taught to first
With proper triage and communication, the prehospital disaster response can successfully reduce the burden of any mass incident on receiving health care facilities. TJC requirements necessitate that hospitals prepare for both internal and external events; these plans should easily be integrated in the event of a combined internal and external disaster. Internal and external events may involve different roles for emergency department (ED) staff. In an internal disaster, the ED’s main focus is generally to treat individuals within the institution who may be injured, with actual management and control of the situation being left to other in-hospital departments.

**Hospital and Agency Disaster Response**

With proper triage and communication, the prehospital disaster response can successfully reduce the burden of any mass incident on receiving health care facilities. TJC requirements necessitate that hospitals prepare for both internal and external events; these plans should easily be integrated in the event of a combined internal and external disaster. Internal and external events may involve different roles for emergency department (ED) staff. In an internal disaster, the ED’s main focus is generally to treat individuals within the institution who may be injured, with actual management and control of the situation being left to other in-hospital departments.

**Fig. 215.3** Combined START (Simple Triage and Rapid Treatment)/JumpSTART triage algorithm. *When using the JumpSTART algorithm, first evaluate all children who did not walk under their own power. A, Alert; CR, capillary refill time (seconds); Delayed, treatment may be delayed for hours to days; Immediate, requires immediate lifesaving treatment; JS, JumpSTART; P, pain; Pedi, pediatric (patient); U, unresponsive; V, voice.*
according to the institution’s incident command protocol. The possibility of ED evacuation should be part of any hospital plan and be well thought out and rehearsed for maximum speed and safety. In an internal disaster, resources and outside aid should be sufficient for patient care and evacuation such that critically ill patients can be treated or evacuated (or both) with highest priority.

External disasters usually result in sudden and often overwhelming volumes of patients at one or more local health care facilities. Ideally, controlled prehospital triage should result in even and appropriate distribution of patients to local hospitals; however, research on a variety of disasters has shown that frequently, the majority of patients do not arrive at hospitals via ambulance. This fact can cause significant disruption of carefully planned dispersion of resources and lead to rapid saturation of the closest or most familiar facilities, as well as difficulty in patient tracking and timely hospital notification. Hospitals should be prepared for significant communication breakdown, restricted access, limited outside help, mass influx of victims with a variety of injuries, and personnel limitations. For example, hospitals in the flood zone of Hurricane Katrina suffered prolonged austere conditions because of protracted physical inaccessibility, primitive communications, and lack of timely outside aid. Other prolonged mass casualty events, such as the 2009 H1N1 influenza pandemic, affect both hospital functioning and the community at large.

**BOX 215.1 Secondary Assessment of Victim Endpoint Protocol Treatment Priorities (in Descending Order)**

- Temporary airway management
- Pressure dressings to stop bleeding
- Simple pneumothorax
- Treatment of shock after control of bleeding
- Advanced airway techniques
- Limb manipulation for vascular supply
- Burns—25% mortality
- Chest trauma
- Spinal injury
- Fasciotomies, amputations
- Open wound care, closure
- Head injury; GCS score ≥ 8
- Abdominal trauma
- Head injury; GCS score < 8
- Burns—50% mortality
- Burns—75% mortality
- Head injury; GCS score 3

and create chronic resource shortages both internally and externally.

When local and regional resources are overwhelmed in a disaster, national governmental and private agencies may be needed for assistance. The largest and most important source of aid comes from the federal government through the DHS. This department was founded after the 2001 terrorist attacks on New York City and combined many different government agencies that were responsible in some way for public health or safety. The Emergency Preparedness and Response subdirectorate of the DHS combined the Federal Emergency Management Agency (FEMA) and the National Disaster Medical Service (NDMS), as well as the Federal Bureau of Investigation, Energy, and Justice Department agencies, to oversee federal disaster response and training. FEMA has several thousand full-time and reserve employees who are responsible for planning and coordinating a federal response to disaster, as well as on-scene deployment of resources. NDMS provides medical assistance to disaster areas in the form of volunteer health care personnel, resources and infrastructure for delivery of care, veterinary and mortuary teams, and prevenet training of first responders. Non-governmental organizations such as the Red Cross (and, internationally, the United Nations) often partner with federal agencies to coordinate response and allocation of resources after catastrophes.

Although FEMA search-and-rescue teams are ideally deployed within 6 hours after declaration of a disaster and can provide basic scene and patient stabilization, federal resources are often delayed for several days. Evidence suggests that local response to disasters has the most lifesaving potential because outside aid generally arrives too late for meaningful immediate medical care.78

WEAPONS OF MASS DESTRUCTION AND HAZARDOUS MATERIALS

Traditional disaster medicine developed mainly in response to natural events such as floods, earthquakes, tornados, and other disasters. However, increasing sophistication and spread of man-made disasters in recent years have brought these types of catastrophic incidents to the forefront of focus and research. Potential agents available to terrorists include chemical, biologic, nuclear, radiologic, and explosive devices (generally referred to as weapons of mass destruction [WMD]); although the overall likelihood of an attack is low, the consequences may be cataclysmic. One gram of botulin toxin has the potential to kill 1 million people,79 and the effects of nuclear and radioactive agents can reach across continents. The response to WMD events may differ significantly from the traditional disaster models described earlier, with shifting priority on decontamination, agent-specific triage, and special resources and personnel.

Preparing for biologic and chemical attacks is difficult and must be adaptive. Disease surveillance programs that link a community are essential for detection and prompt response because biologic agents may not be detected for days to weeks.80,81 Predisaster emphasis should be on hazard analysis, as well as training and stockpiling of antidotes for the most likely agents to be used. The Strategic National Stockpile is a national reserve of medical supplies, antidotes, and medications managed by the Centers for Disease Control and Prevention and strategically placed in states for rapid availability following a mass casualty event.

In both biologic and chemical attacks, early evacuation and containment of the “hot zone” (the area of maximum contamination) is critical to mitigate injuries and spread. The hot zone should have a clear and strict entry and exit, separate “clean” and “dirty” areas, and continuous monitoring. Primary emphasis should be given to decontamination and safety of first-responder personnel, not only to ensure a strong medical response but also to limit unintentional dissemination of the contaminant. Accurate risk assessments should be communicated to the public and updated frequently.

Traditionally, preparation for WMD has used the more common hazardous materials (HAZMAT) exposure training methods. These models may not, however, be appropriate.64,82 HAZMAT events assume an exposure away from health care facilities, where response teams with maximum personal protection and extensive decontamination equipment work to rescue and decontaminate small numbers of victims. Large-scale exposure to WMD may encompass public areas and health care facilities, thereby compromising response efforts and calling into question the traditional decontamination methods.83 For example, in the 1995 Japanese subway nerve gas attacks, several thousand people were potentially exposed, yet fewer than 100 were killed or seriously injured. However, thousands arrived at hospitals by private vehicle without on-scene decontamination, which quickly overwhelmed the facilities and potentially exposed scores of essential medical personnel.80

THE ROLE OF EMERGENCY PHYSICIANS IN DISASTER MEDICINE

Published ACEP policy advocates a leadership role for emergency physicians in all aspects of disaster research, planning, and implementation.84 The traditional focus of disaster medicine—to do the most good for the greatest number of people—may seem to be at odds with the traditional emergency medical principles of aggressive resource utilization for selected critically ill patients. However, the emergency physician is generally the best-trained individual to coordinate medical control, supervise triage, connect with other municipal and public health agencies, and oversee direct patient care during a catastrophic event. Several formal disaster medicine fellowships exist for emergency medical physicians, and disaster training is included in the emergency medical residency curriculum. Advances in research and increased global attention to natural and man-made disasters create exciting potential for emergency physicians to lead the development of disaster medicine as a discipline.

Patient-Centered Care
Kevin Klauer and Kirsten G. Engel

216

KEY POINTS

- Patient-centered care is an approach to patient-provider interactions in which providers work together with patients and their families in an effort to ensure that the patient’s personal experience and preferences are an integral part of the care process.
- A patient-centered approach to care confers many benefits in the acute care setting and can be critical in overcoming barriers to the communication process in the emergency department.
- The practice of patient-centered care involves both personal elements that individual providers can integrate into their daily interactions, as well as system-level elements that can be implemented and supported on the departmental and institutional level.

BACKGROUND

The concept of PCC gained attention with the influential Institute of Medicine reports in 1999 (“To Err Is Human”) and 2001 (“Crossing the Quality Chasm”). The first report outlined mechanisms to improve patient safety, including efforts to engage patients in their care and enhance their understanding of their treatment. Two years later, “Crossing the Quality Chasm” identified PCC as one of the six aims intended to improve the quality of health care in our country.

In 2006, the American College of Emergency Physicians (ACEP) and the American Academy of Pediatrics issued a joint policy statement supporting patient and family-centered care as an important means of improving satisfaction, safety, and quality of care for patients and their families.

The emergency department (ED) environment is inherently challenging to the communication process between patients and providers, and a patient-centered approach to care can be particularly valuable in this setting. ED providers routinely confront significant time constraints, unpredicted interruptions, and overcrowding while caring for patients with life-threatening illness and injury. Given these circumstances, it is essential that ED providers possess skill in rapidly establishing rapport and engaging patients in critical decision making. A patient-centered approach to care is vital in overcoming barriers to the communication process through an understanding of the many situational and personal factors that characterize a patient’s visit to the ED. In many cases, fear, anxiety, and uncertainty, as well as preconceived and often unrealistic expectations, play an important role, and these factors must be recognized and appropriately managed to effectively communicate with patients.

A patient-centered approach to care provides clear benefits to the immediate patient-provider interaction, but it also appears to have a positive impact on important outcomes for the patient and provider. Although research in this area is challenging, early work indicates that PCC improves patient satisfaction and may also enhance adherence and health outcomes.

INTRODUCTION

Patient-centered care (PCC) is an approach to patient-provider interactions that promotes a collaborative partnership among health care providers, patients, and their families. In clinical practice, emphasis is placed on understanding patients and their clinical presentation within the larger context that includes their family, personal views, preferences, values, past experiences, and cultural factors. By embracing each patient as an individual, a patient-centered approach seeks to ensure high-quality care that consistently meets the needs and preferences of patients and their families.

GOALS

The goals of this chapter are as follows:

1. To review the evolution and core features of PCC and its importance to clinical practice in emergency medicine
2. To discuss practical, realistic approaches and strategies in the following three domains of daily clinical practice, which can facilitate the delivery of PCC:
   a. Personal issues—practice considerations for the individual provider that can promote PCC
   b. Systems issues—practice considerations on a departmental level and from a systems perspective that can promote PCC
   c. Critical issues—practice considerations for special circumstances when PCC can be particularly important

PERSONAL ISSUES

As individual providers, there are many simple things that we can do every day in the ED during our patient interactions that facilitate the provision of PCC. The following sections highlight practical approaches and strategies that can be realistically incorporated into clinical practice on a daily basis. Our discussion will consider three areas: communication, operational considerations, and humanistic considerations.
COMMUNICATION

Communication is the process of information exchange and is a central and critical aspect of our care of patients in the ED. As providers, we must solicit and receive information, establish the diagnosis, understand the social situation, and make an appropriate plan for care. In addition, we must provide patients with information to facilitate understanding of their treatment and diagnosis, improve adherence to instructions, and ensure good outcomes.

Communication has two major components: verbal and nonverbal. These components work together and complement one another, with both having an impact on information exchange.

Verbal communication in our interactions with patients includes several key elements:

1. Introduce yourself, including your name and role.
2. Allow patients to speak and complete their thoughts while avoiding interruptions whenever possible. Be sure that you address all the patient’s medical concerns.
3. Use clear, nontechnical language.
4. Give patients the opportunity to ask questions.
5. Review information to confirm patient understanding (i.e., treatment, diagnostics, follow-up, discharge instructions).

Nonverbal communication is just as powerful as verbal communication with respect to its impact on patient-provider interactions. Facial expressions, body language, and physical space or touch are several aspects of nonverbal communication. Although nonverbal communication is more subtle and may seem less vital than verbal communication, it is essential to recognize the importance of nonverbal elements and their role in supporting or undermining the words that we use. This component is particularly critical in our efforts to convey courtesy, compassion, and respect.

Nonverbal communication in our interactions with patients has several key elements:

1. Greet patients and family members with a handshake when appropriate.
2. Make consistent eye contact and commit your complete attention to the interaction.
3. Use calm, compassionate body language.
4. Consider appropriate use of physical touch to provide comfort while being sensitive to cultural issues.
5. Avoid nonverbal cues of discontent.

OPERATIONAL CONSIDERATIONS

Interactions between providers and patients progress through several important stages of the ED visit. Provision of PCC relies on effective engagement of patients during each of these critical junctures. Although a systems approach to PCC is discussed later in this chapter, some practical considerations for incorporating patient-centered care into daily practice are reviewed here and include examples of appropriate phrases and statements for each stage of the ED visit.

Intake

When a patient first enters the ED, it is critical to engage the patient quickly with effort to minimize time between arrival and the first interaction. Patients often feel anxious or frightened by the ED environment and typically experience distress and frustration because of the event or abrupt change that has prompted the need for their visit. Providers should be sensitive to these feelings by immediately delivering expressions of caring and concern, acknowledging the patient’s discomfort and circumstances, and providing reassurance.

“I am sorry to hear about your injury (or that you are not feeling well). We are happy that you are here and will work as quickly as possible to help you feel better.”

Assessment

During the initial assessment phase, it is important that patients be given the opportunity to express their concerns and symptoms and to feel that they have been heard. Repeating a brief summary and highlighting patients’ key issues can help assure them that their concerns are being given appropriate consideration.

“So, let me make sure that I’ve heard everything you said about your symptoms. As I understand it, you have had …”

As the diagnostic and treatment plan is developed, it is also important that this plan be shared with the patient and that there be clarity and agreement about the intended testing strategy, its anticipated duration, and overall expectations for the visit and ultimate disposition. This approach facilitates a collaborative relationship between the provider and patient, which is a key element of patient-centered care.

“In order to better understand what might be causing your symptoms, we are going to do a series of tests, including … This is expected to take … I will come back and talk to you about the results when I receive them.”

Waiting and Delays

In any situation, when a patient needs to wait or experiences a delay in care, it is vital that providers reconnect with the patient and provide explanations and reassurance. Previous research has demonstrated that patients have greater tolerance for these circumstances if they are well informed about the causes and the anticipated duration.

“I know you are waiting, and I want to make sure you know that we have not forgotten about you. We expect that …”

Disposition

When the evaluation has been completed, and patients are ready for discharge or admission, it is critical that the treatment and management plan be reviewed with them in detail and that they be given the opportunity to ask questions. Using an open-ended statement to elicit questions may help set an expectation that questions are welcome and anticipated.

“What questions do you have?” may be preferable to a more closed approach such as “Do you have any questions?”

HUMANISTIC CONSIDERATIONS

An additional core element of PCC is the consideration of a patient’s illness and signs and symptoms in the larger context of the patient’s personal experiences and background. As providers, we are well aware that similar illnesses or conditions can yield diverse reactions and responses in different patients or populations. These differences reflect variation in patients’ personal views, cultural beliefs, preferences, values, past experiences, and fears. Provision of PCC means simply that we do not disregard these differences but, instead, actively seek to understand them, embrace them, and incorporate them into our clinical practice and plan of care. We should view...
each patient as an individual (not a disease process or diagnosis) and recognize that each brings a unique story and circumstance to the ED.

In the real world, these humanistic elements of PCC are often met by important challenges. We discuss these issues here and consider how one can begin to recognize and minimize such barriers to the practice of PCC in a busy ED.

**Time: Making the Most of What We Have**

All too often, ED providers face time constraints and significant clinical demands that are perceived as obstacles to providing care with a humanistic approach. It seems impossible for us to have the time to explore individual patients’ personal experiences, values, or beliefs.

Although it is not easy to create more time during a busy shift, we can make sure to take advantage of the opportunities that we do have and optimize our available resources. During assessment and evaluation in the ED, patients often share thoughts and give small clues that are important to understanding their social situation, motivation, and values. We need to be sure to explore these avenues because this additional information can help us connect with our patients and create a plan that better incorporates their perspectives and needs. This extra effort may prevent the conflict or frustration that will lead to larger, more time-consuming obstacles and challenges. Each of us can surely think of a situation in which we disregarded a patient’s expression of anxiety or uncertainty about a plan (e.g., admission to the hospital) that later resulted in a difficult and prolonged interaction (e.g., trying to convince the patient to go upstairs when the bed was ready).

In addition, ED providers need to enlist the support of all available resources, including social workers, nursing staff, and consulting services, to evaluate and support each patient’s needs. These interactions can help us better understand our patients and their personal circumstances, even when we are unable to pursue this level of detailed information independently.

Overall, it is important to keep in mind that “technically excellent” patient care (including the “right” diagnosis, correct management plan, and appropriate disposition) is not “the best” patient care unless it reflects some understanding of the patient’s personal story.

**Provider Emotions: Leaving Our Personal Reactions and Feelings at the Door**

As is true for our patients, providers have a history and past personal and professional experiences that can lead to intense emotional responses. When we care for patients, our personal feelings, reactions, and judgments can significantly influence how we interact with patients and families. To provide PCC, it is critical that we learn to acknowledge our feelings, recognize how they are affecting us, and minimize any negative impact that they may have on our patient-provider encounters.

**SYSTEMS ISSUES**

Historically, the care provided in most health care settings has been provider-centric and focused on flow and outcomes from the provider’s perspective. The ED is no exception. Until recently—the last decade and especially in the past few years a patient-centered approach to care was seldom considered in ED operations, and when it was, its weight and priority were often too far down the list to be given serious consideration. However, the tide has turned. Patient satisfaction has been recognized as a driver for hospital market share. Not surprisingly, the topic in patient satisfaction surveys most important to hospital administrations is the likelihood to return or refer others. This focus on patient satisfaction has helped prompt a change in the culture of medicine that has resulted in PCC. Although satisfying our patients to improve hospital market share is important, it is not the only factor influencing this shift in paradigm. The current state of our medical-legal system, compliance with governmental regulations (including pay-for-performance initiatives), and the demand for operational efficiency are all critical stimuli for turning to an approach that is patient centered. Although patient-centered care can be provided on a case-by-case basis, a systems approach is necessary to develop a patient-centered culture.

**PATIENT SATISFACTION**

Satisfying patients is at the core of developing a culture that is patient centered. Although many providers will summarily dismiss the value of the patient’s perception of the care rendered, this viewpoint is only partially valid and is misguided. Certainly, patients are not qualified to judge the technical adequacy of the medical care provided. However, they are more than qualified to judge whether the system and providers cared about their comfort, communicated their treatment plans, addressed their pain, and informed them about wait times and delays. It should not be a surprise to anyone that these same concepts are represented in almost every commercial and noncommercial patient satisfaction survey tool currently in use.

So, EDs need to be in the business of making patients happy. Those that are not will quickly learn that their competitors are more than happy to do so. The ED is the operational “front door” of most hospitals. In 2008, the National Ambulatory Medical Care Survey, 2006, reported that the ED was the source of 50.2% of all nonobstetric admissions to U.S. hospitals. Furthermore, if an ED is not interested in making a good impression on the community and embracing patient satisfaction as a core competency, many chief executive officers will look for ED staffing solutions that will provide the appropriate emphasis on this important goal. Although individual interactions can be standardized and scripted to improve patients’ experience, as discussed previously, operational efficiency goes a long way toward pleasing patients.

Common themes in the literature are that provider interpersonal communication skills, delivery of information and explanations, and perceived wait times most strongly correlate with patient satisfaction. Although actual wait times are less likely to predict satisfaction or a lack thereof, patients with a length of stay of 8 hours are generally less satisfied than their counterparts waiting only 4 hours. Operational efficiency is not only critical to ensuring patient satisfaction but is also a key factor associated with a patient-centered approach to care.

**OPERATIONAL EFFICIENCY**

Operational metrics such as overall length of stay, door-to-provider time, provider-to-decision making time, and decision making-to-disposition time are nationally recognized
measures of operational efficiency. These metrics should be measured and performance improvement initiatives tailored toward a more efficient experience for the patient.

Operational efficiency not only provides a positive impact on patient satisfaction but also promotes patient safety; both are critical to PCC. In other words, patients are happier when they are seen more quickly and have a shorter length of stay. In addition, when throughput is more efficient, an ED’s bed capacity can be used more effectively, more patients can be seen, patients who leave without being seen can be avoided, and the likelihood of deterioration of patients in the waiting room can be reduced. For instance, if the average length of stay for admitted patients is 6 hours in one ED versus 3 hours in another, with both seeing 50,000 patients a year and having 40 ED beds and an admission rate of 50%, 205 patient care hours would be saved in the more efficient ED on a daily basis. Thus, the more efficient ED can see 68 more admitted patients than the less efficient ED. Of course, the operational efficiency of admitted patients is dependent on many factors inside and outside the ED.

A truly patient-centered culture will address ED crowding and ED boarding of admitted patients as a hospital system issue, not an isolated ED issue. We know that boarding often results in inefficient bed management in the hospital and leads to delays in the time that it takes to execute a decision for admission. A policy statement released by the ACEP in January 2011 clarified the definition of boarded patients: “In order for emergency departments to continue to provide quality patient care and access to that care, ACEP believes a ‘boarded patient’ is defined as a patient who remains in the emergency department after the patient has been admitted to the facility, but has not been transferred to an inpatient unit.”

Furthermore, it has been proved that the heavy demand on ED resources during times of crowding is an impediment to providing high-quality care and compromises patient safety. Although a thorough discussion of throughput metrics is beyond the scope of this chapter, it is important to note the critical nature of these metrics when considering the patient as the primary stakeholder in these processes.

The time from decision making to actual disposition (departure from the ED) may be viewed by many as being beyond the control of the ED, as well as by many institutions that do not view boarding as an institutional issue. However, intake is a process that is solely owned by the ED. Yes, intake processes are adversely affected by boarding and lack of availability of hospital resources, but nimble EDs can create the necessary “work-arounds” to stay patient centric in their approach. Bedside registration is an excellent tool to improve door-to-bed times. Registration is often a non–value-added step, from the patient’s perspective, that is frequently placed ahead of patient care. Not only does this have potential Emergency Medical Treatment and Active Labor Act (EMTALA) implications, it also delays the care provided. Because there is often considerable downtime during an ED visit, it is ideal for the registration process to be conducted during these times, not at the critical front-end portion of the visit. Some would argue that care cannot begin until a chart can be generated and ordering in the hospital’s information system can begin. This argument holds no water because very little information is actually needed to generate a patient identification capable of initiating care, and this information can be obtained during the triage process.

The shortfall is that bedside registration does not ensure that a provider will get to patients any quicker than if they were in the waiting room. Thus this may not affect the more important metric of door-to-provider (doctor) time. However, placing a provider in triage does. Whether a physician or midlevel provider, placement of a provider at triage with the nurse can initiate the visit without the need for formalized ED bed placement. Furthermore, many low-acuity patients may be discharged directly from triage, after completion of their care, and never need an ED bed. Standing orders may be a bridge to initiate care. However, standing orders are often overly broad in application and result in unnecessary tests being ordered, and they do not take the place of the provider in evaluating and initiating management of the patient.

**MEDICAL-LEGAL FACTORS**

The two primary factors associated with filing medical malpractice claims or lawsuits are bad patient outcomes and unhappy patients. Although the relatively frequency of medical malpractice claims is fairly low, with a range of approximately 1 in 25,000 to 40,000 ED encounters, it is difficult to find definitive correlations between patient satisfaction and lawsuits. However, the preponderance of the literature more than strongly suggests that poor patient satisfaction results in more patient complaints. Additional data suggest a strong correlation with patient complaints and risk management events and medical malpractice lawsuits. In one study, a 1-point decrease in patient satisfaction survey results correlated with a 6% increase in the incidence of risk management events (claims, lawsuits, and incident reports). In this same study, 75% of 483 claims were associated with communication errors, thus emphasizing the need for improved communication between patients and providers. Patients who are well informed about their care are less likely to be taken by surprise by changes in their condition, medication side effects, and failure of treatment. To that end, treatment and diagnostic plans should be discussed with patients and their significant others, results should also be discussed with them, therapeutic response to treatments needs to be assessed, and final disposition plans need to be discussed and agreed and comprehension acknowledged and confirmed. Although many busy EDs defer some of these tasks to nursing, it is of vital importance that the physician at least reinforce these communications. However, it is ideal for the physician to be the primary provider to conduct communications with the patient.

Patient handoffs are another aspect of a patient-centered culture that is both an operational and a risk management concern. Up to 24% of medical malpractice claims result from faulty handoffs. Handoffs are transitions in care from one provider to another and often from one care setting to another. To ensure that errors are avoided, the quality of care is not compromised, and patient safety is preserved, a standardized approach should be taken to handoffs in the ED. Recommended steps include a face-to-face encounter by the incoming and outgoing providers, an explanation of the active problem list and any outstanding diagnostics, and the expectations for disposition. In addition, it is useful to advise the patient that the handoff is occurring and even introduce the patient to the incoming provider.

Yet another new focus on PCC that is intertwined with risk management is error disclosure. Disclosing errors is now
a patient safety requirement from the Joint Commission. Concealing medical errors is unethical, immoral, and unwise. Furthermore, every hospital must have a policy outlining the requirements for disclosure of medical errors. The decision to disclose should not be based on the severity of the error or the provider’s perception of patient impact. If the error occurred, the patient has the right to know that it occurred, regardless of how others value the importance of this information. Such a policy should include notification of the hospital risk manager and ED leadership (i.e., medical director, nurse manager). It is also important to note that disclosure is an excellent risk management tool. Appropriate settlements can be reached, litigation avoided, and indemnity and defense expenses reduced. Moreover, if a medical error is concealed and a lawsuit is filed, the error will invariably be identified through the discovery process. Once it appears that the providers intended to “cover up” the error, there is no viable defense, and no jury in the United States will be sympathetic with defendants who were flagrantly dishonest.

**COMPLIANCE**

The federal government has long been interested in PCC. Consider the patient implications with the Civil Rights Act of 1964, the Health Insurance Portability and Accountability Act (HIPAA), and EMTALA. Clearly, the federal government has embarked on many initiatives that are patient centered. The Civil Rights Act requires that any institution accepting federal compensation for rendered care must provide medical interpretive services for limited English-proficient patients. Not doing so is in violation of this statute and may constitute civil rights violations on behalf of the patient. Medical interpreters are not only required to be fluent in the language that they are interpreting but must also have experience in medical interpretation. In other words, finding someone in the hospital who speaks a language (i.e., a Spanish-speaking housekeeper) is not sufficient. It is also important to recognize that the use of family members is not a viable substitute unless the patient refuses formal medical interpretation. If there is a problem, complaint, or bad outcome, the only witness to the interaction between providers and the patient will be the interpreter. It is unwise for that sole witness to be a nonimpartial family member.

HIPAA focuses on the patient’s right to due care being given to their protected health information. This information, sensitive to the patient, must be handled in accordance with this statute to protect the patient’s privacy. EMTALA requires that all patients who go to the hospital, its “campus,” and related buildings with an emergency medical condition have a medical screening examination (MSE) performed, regardless of their ability to pay. The MSE also includes stabilization of any identified emergency medical condition. Thus, through the course of compliance and performing the MSE, the care of most ED patients is completed. Though not a financially viable program for hospitals and emergency medicine, it is certainly a patient-centered initiative that allows access to care for all emergency patients (Box 216.1).

Compliance with federally mandated programs is essential for a hospital to maintain an individual provider’s Medicare provider number. Without these numbers, participation in federally funded programs such as Medicare and Medicaid is prohibited.

---

**BOX 216.1 Operational Strategies for Patient-Centered Emergency Care**

- Minimize door-to-doctor time.
- Initiate diagnostics as soon as possible after arrival (by physician evaluation, provider in triage, or standing orders).
- Assess and address pain promptly.
- Build processes to notify the physician of returned results and prompt delivery of the results.
- Promote diagnostic efficiency (only appropriate testing, obtaining laboratory tests at the time of insertion of an intravenous line).
- Make decisions promptly once sufficient data have returned.
- Use computerized discharge instructions at the second-grade educational level (language appropriate).
- Provide medical interpretive services (also avoids violation of the Civil Rights Act of 1964).
- Formalize processes for disclosure of medical errors.
- Draft policies for EMTALA compliance.
- Draft policies for HIPAA compliance.
- Formalize the patient handoff process.
- Formalize the approach to and emphasis on patient satisfaction.
- Foster a culture of excellent communication.

*EMTALA, Emergency Medical Treatment and Active Labor Act; HIPAA, Health Insurance Portability and Accountability Act.*

---

**CRITICAL ISSUES**

**ADVANCED DIRECTIVES**

In the ED setting we frequently care for patients with life-threatening illnesses who are faced with important choices regarding their management. As emergency providers we need to develop skill in helping patients and their families understand their disease and prognosis, consider the acute issues that they are confronting, and make choices that reflect their personal priorities and goals. The process of discussing and establishing goals of care is a large and important topic that incorporates many of the core principles of PCC. Advanced directives represent a critical subset of this area that we encounter frequently and often cannot be deferred to a later time.

As we approach a patient and family for a discussion of advanced directives, we should be guided by the fundamental elements of PCC. We must embrace our patients (and their families) as unique entities and consider their personal story and circumstances as we provide clinical information and guidance in their decision-making. With this approach we are able to support the patient and family in choosing the best path for them while recognizing that there is no absolute “right” choice or plan.

**FAMILY-WITNESSED RESUSCITATION**

Interest in the practice of family-witnessed resuscitation (FWR) began in the 1980s after studies surveying families of survivors of sudden death found that their most frequent criticisms centered on frustrations with inadequate information and updates during resuscitation. Additionally, it was noted that families of critically ill or dying patients often complained about feeling helpless, uninformed, and
uninvolved.\textsuperscript{18} As a result of these findings and some requests by family members to be present during resuscitation procedures, standard practices excluding families began to come into question.\textsuperscript{19,20}

Within the field of emergency medicine there has been significant debate regarding whether families should be allowed to accompany their relatives who are undergoing critical resuscitation. Proponents of this practice advocate that family members should have the choice to be present during these desperate efforts, which are often the final moments of patients’ lives. However, many medical professionals are strongly opposed to the idea and cite a wide range of concerns: that relatives will interfere with or misunderstand medical efforts, that the events will be too upsetting for relatives to bear, and that family presence will create additional stress and anxiety for the medical team.\textsuperscript{21-25}

Research to date demonstrates that families who are allowed to be present during resuscitation procedures recognize the practice as beneficial to both themselves and their ill relatives. Family members perceive their presence as important not only to provide support and reassurance to the patient but also to relieve their own anxiety by reducing feelings of helplessness and the “agony of waiting.”\textsuperscript{26} Relatives also report that being present with a dying loved one eased their subsequent bereavement process.\textsuperscript{20,26,27}

Research findings also indicate that the anticipated problems or expected complications of FWR fail to occur in clinical practice.\textsuperscript{27,29}

In recent years FWR has been recognized as being fundamentally consistent with a patient- and family-centered approach to care.\textsuperscript{30} FWR provides the opportunity to engage and empower a patient’s loved ones during the most critical moments of serious injury or illness. The open door facilitates a connection and partnership between the provider and family that can have significant downstream effects on this relationship and, ultimately, the grief and bereavement process.

In the future, more research is needed to fully assess the consequences of FWR for all participants in the resuscitation process and for different clinical situations and patient populations. However, it is clear that research alone will not resolve this debate because our emotional responses as providers may defy research results. As emergency providers we must focus our energy on helping ourselves and others remain open-minded to the possibility of benefit from these practices and consider their role in our efforts to provide patient- and family-centered care.

**INFORMED REFUSAL**

In emergency medicine we often encounter patients who refuse our recommended care, and our interactions with these individuals can be frustrating and challenging. Many factors can lead to refusal, and ultimately we must accept a patient’s choice to refuse our recommendations. However, when we encounter these situations in our daily practice, a few important concepts should be considered.

First, we must work hard to ensure that we use the basic principles of PCC in our efforts to discuss this issue with our patients. We must explore the situation from their perspective—their past experience, social circumstances, fears, and anxiety—to help us understand the factors that are leading to their refusal. Second, we must set aside our personal reactions and feelings as we engage in these interactions. In particular, we cannot allow our own emotions and responses to patients prevent us from making a genuine effort to connect with them and to help them understand how our recommendations may be compatible with their personal views and preferences.

In the end, we must accept that sometimes our efforts will not be successful and we have to understand how to approach these situations. Informed refusal stems from the doctrine of informed consent, and the same basic tenets apply. Patients need to possess the medical decision-making capacity to consent or refuse care (e.g., conscious, alert, and oriented to person, place, time, and situation), and they need to be informed of the risks and benefits of the proposed treatment and the risks and benefits of alternatives, including no treatment at all. Patients need to demonstrate their understanding of this discussion. The standard for informed consent or refusal is what a reasonable patient would want to know. This is vastly different from the former physician standard regarding what a reasonable physician would inform the patient about. Informed refusals should be well documented in the medical record, and it is important to recognize that signing a refusal or against-medical-advice form does not necessarily meet the required elements for informed refusal. Merely signing a form does not document which risks associated with refusal were discussed with the patient.

**CONCLUSION**

PCC is emerging as a primary initiative in many care settings. The ED is no exception. Whether the goal is patient satisfaction, improved patient safety, reduced risk, improvement in hospital market share, operational efficiency, or compliance with governmental mandates, patient-centeredness is the correct focus and emphasis for the future. Any initiatives considered should first be vetted in the context of the patient’s perspective and the impact that such endeavors may have on the patient. What is wrong for our patients is wrong for us.

INTRODUCTION

As the globalization of trade, technology, investment, and migration create a more diverse U.S. population, we are increasingly becoming aware of disparities in economics, health care, and human rights. Our nation was founded on the concept that “all men are created equal,” and equal treatment and equal access are the goals toward which we strive. Nowhere else in medicine is the commitment to equality as obvious as it is in emergency departments (EDs), where the sole criteria for moving to the front of the line is severity of illness. Other specialties now restrict the days and hours during which they are available to patients and tell their patients at discharge from the hospital to go to the ED if they have any problems or concerns. Changes in the economy have resulted in a significant increase in the percentage of uninsured. Only the ED provides medical care 24 hours a day, 365 days a year for every patient with any complaint. As advocates for our patients, emergency physicians (EP) are at the forefront of the promotion of diversity and the elimination of disparities in health care, not just at home but throughout the world.

The definitions of some important terms, broadly and more specifically as they relate to emergency medicine (EM), will help provide a common understanding and language for the reader (Box 217.1). Awareness of the history of disparities in access to quality health care (Box 217.2), the benefits of clinical research (Table 217.1), and medical education and EM practice (Box 217.3) will create a contextual framework within which the reader can appreciate all that has been accomplished, as well as the tasks that remain, as we work toward the ideals of diversity and cultural competency.

IDENTIFYING ISSUES OF DISPARITY

In 2003 the Institute of Medicine (IOM) was charged by Congress to examine racial and ethnic disparities in health care. Their landmark report, “Unequal Treatment: Confronting Racial and Ethnic Disparities in Healthcare,” brought the issue of health care disparities to national attention. The report concluded that “Racial and ethnic minorities tend to receive a lower quality of healthcare than non-minorities, even when access-related factors, such as patients’ insurance status and income, were controlled.” The report defined disparities as “racial or ethnic differences in the quality of healthcare that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention.”

According to the U.S. Census Bureau, there are currently more than 300 million Americans: 65% white, 16% Hispanic, 13% black, 5% Asian, and 1% American Indian. Yet according to a report by the American Medical Association, only 6.4% of practicing physicians are Hispanic and 4.5% are black. Recognizing the changing patient demographics and the unchanging demographics of the physician workforce, the Association of American Medical Colleges (AAMC) Executive Council adopted a definition of underrepresented in medicine (URM) as “those racial and ethnic populations that are under-represented in the medical profession relative to their numbers in the general population.” Before this, the AAMC used the term “under-represented minority,” which specifically targeted African Americans, Mexican Americans, Native Americans, and mainland Puerto Ricans. A much broader definition of diversity includes race, ethnicity, socioeconomic status, sexual orientation, religion, disability, age, language, and geographic diversity.

UNDERSTANDING CULTURAL COMPETENCY

Diversity and cultural competency have emerged as the two main forces for eliminating disparity in medicine. When
patients have contact with the health care system, they bring
their culture and all that it encompasses, including their
beliefs, values, identity, and links to the community. When
people of different cultures and backgrounds come together,
diversity is achieved. The Office of Minority Health (OMH)
defines cultural and linguistic competence as "a set of congru-
ent behaviors, attitudes and policies that come together in a
system, agency or among professionals that enables effective
work in cross-cultural situations." The educational concepts
for cultural competency are centered on the provider's ability
to acquire the knowledge, attitude, and skills necessary to
incorporate it into the medical decision-making process. Ulti-
mately, this concept empowers the physician to navigate the
cross-cultural experience with any patient from any cultural
background by enabling greater understanding of the patient's
perspective and social context. The OMH published their stan-
dards for culturally and linguistically appropriate services
in health care in 2002. Another conceptual model by the
Agency for Healthcare Research and Quality describes how
integrating nine major cultural competency techniques can
test potential improve the ability of physicians and health care
systems to deliver appropriate services to diverse
populations.

BOX 217.1 Definitions

**Culture:** Customary beliefs, social forms, and material traits
of a racial, religious, or social group; also, the character-
istic features of everyday existence shared by people in
a place

**Disparity:** Lack of parity, the state of being dissimilar or
unequal

**Diversity:** Inclusion of different types of people in a group or
organization

### BOX 217.2 History of Health Care Disparities

- **1619-1865:** Contaminated drinking water led to frequent outbreaks of disease among slaves. Slaves develop a system of care involving indigenous herb root doctors and midwives.
- **1824:** The Bureau of Indian Affairs is established and provides limited health care to Native Americans on reservations.
- **1852:** The first hospital for the care of blacks is opened: Jackson Street Hospital, Augusta, Georgia.
- **1862:** The only government-funded hospital for blacks, Freedmen’s Hospital in Washington, DC, is established.
- **1948:** Executive Order 9981 mandates the integration of Veterans Administration hospitals.
- **1955:** The Indian Health Service is commissioned.
- **1965:** The Johnson administration announces that federal Medicaid and Medicare payments will be denied to segregated hospitals.
- **1990:** A metaanalysis of 485 articles confirms that migrant health care is confined almost exclusively to charity migrant clinics and virtually nothing is known about the health status of the workers.
- **2004:** At every age, blacks have higher blood pressure than nonblacks.
- **2005:** A total of 16.5% of American Indians, 10.4% of Hispanics, and 6.6% of whites are diabetic.
- **2006:** African Americans are more likely than whites to die of coronary artery disease. They and Hispanics are less likely to be offered bypass or angioplasty. Blacks have worse cancer survival rates, are more likely to undergo amputation for complications of diabetes, and are less likely than whites to be referred for transplant evaluation. Hispanics and Native Americans are least likely to be offered cholesterol management services.
- **2009:** Of all patients in whom human immunodeficiency virus infection was diagnosed this year, 52% were black.
- **2010:** Twenty percent of the population lives in rural areas, where only 9% of physicians practice.
**BOX 217.3 History of Disparities in Medical Education**

1783: Dr. James Durham, a former slave, becomes the first African American physician. He sets up practice in New Orleans after apprenticeship training.

1837: Dr. James McCune Smith is the first African American to obtain an MD degree. He has to go to the University of Glasgow to do so. He sets up practice in New York City.

1847: Dr. David J. Peck is the first African American to graduate from a U.S. Medical School (Rush Medical College).

1849: Two African American men receive MD degrees from Bowdoin College, Maine.

1850: There are 13 African American doctors: 9 in New York City and 4 in New Orleans.

1857: Dr. Elizabeth Blackwell becomes the first woman to graduate from a U.S. medical school and founds the New York Infirmary for Women and Children.

1867: Dr. Blackwell founds the Women’s Medical College of Pennsylvania.

1868 and 1876: Eight Negro medical schools were established, but only two are still open: Meharry, Tennessee (1876), and Howard, Washington, DC (1868).

1889: Dr. Susan La Flesche Picotte is the first American Indian woman to earn an MD degree; she receives it from the Women’s Medical College of Pennsylvania.

1890: There are 909 African American doctors, as compared with 1734 in 1900 and 4500 in 1960.

1891: Dr. Daniel Hale Williams opens the first black-owned hospital ( Provident Hospital in Chicago).

1905: Being denied membership in “mainstream” medical associations, Dr. Williams establishes the National Medical Association.

Over the course of time there has been an evolution in the education and assessment of cultural competency in undergraduate and graduate medical education. The Liaison Committee on Medical Education has codified the following criteria: “Students must demonstrate an understanding of the manner in which people of diverse cultures and belief systems perceive health and illness and respond to various symptoms, diseases, and treatments.” Similarly, the Accreditation Council for Graduate Medical Education (ACGME) has defined its competency standards within two of the six core competencies: patient care and interpersonal communication skills.

**MOVING TOWARD JUSTICE IN RESEARCH**

Even though access to care has improved remarkably for racial minorities over the past 2 centuries, it is important to realize that they “are disproportionately affected by multiple barriers to care: financial, linguistic, cultural, logistical, organizational, institutional and systemic. Disturbingly, providing disadvantaged populations with adequate access to care may not be sufficient to eliminate racial/ethnic disparities in health.”

In the Health Disparities and Inequities Report of 2011 by the Centers for Disease Control and Prevention, minority groups were overrepresented in every diagnostic category monitored except suicide and drug-induced death, where whites prevailed. To highlight the importance of patient-centered, culturally competent care, the AAMC developed the Tool for Assessing Cultural Competence Training (TACCT), which provides a framework for designing, implementing, and integrating an effective cultural competency educational program.

The TACCT is a self-administered assessment tool that can be used to identify the strengths and weaknesses of a program’s educational curriculum. ACGME’s Toolbox of Assessment Methods is an excellent resource that includes assessment methods and references to articles where more in-depth information can be found. The design, implementation, and assessment of effective cultural competency curricula must be flexible, be tailored to the institution, maximize existing resources, and be linked to a data collection component to measure and monitor for success.

The 2003 Academic Emergency Medicine national consensus conference “Disparities in Emergency Health Care” went further by addressing issues of unconscious personal bias, disparities profiling, and the need for epidemiologic and clinical research directed at making an impact on outcomes and improving physician-patient communication.

**EXPLORING SOLUTIONS**

The Sullivan Alliance, composed of former members of the IOM and the Sullivan Commission, a group commissioned by Duke University and the Kellogg Foundation to study diversity in the health care workforce, aimed to transform the health professions by providing a comprehensive framework of 62 recommendations from both reports. The AAMC has led several efforts targeted at the critical steps referenced by the Sullivan Alliance. Recognizing the challenges that medical schools and academic medical centers face when implementing the recommendations, the AAMC published several road maps that highlight some of the legal, practical, and subtle barriers and describe the different levels of commitment required throughout the organization.
inadequate inclusion of blacks and Hispanics in research on human immunodeficiency virus. Because trauma is predominantly a disease of racial and ethnic minorities, the poor, and the undereducated and because these populations are regarded as vulnerable by IRBs, there are significant barriers to conducting trauma research. Several EM researchers have questioned whether there exist vulnerable populations in conditions in which acute loss of decisional capacity makes all patients equally vulnerable. Others question whether the standard informed consent process, refused more often by black than by white patients, may not introduce bias into research studies by underrepresenting disease among minority patients. Because EM research is predominantly conducted by EP scientists, our specialty must continue to take the lead in ensuring that all patients have equal access to the benefits of research while being equally respected and protected from potential abuse.

MOVING TOWARD DIVERSITY IN MEDICAL EDUCATION AND PRACTICE OF EMERGENCY MEDICINE

Increasing the diversity of the medical student population and ensuring that physicians are trained to be culturally competent have been cited as key strategies in addressing health care disparities and preparing health care systems for the challenges of the 21st century. The concept of concordance, another factor in favor of increasing diversity of the physician workforce, has been well documented in the literature. Yet despite increasing evidence of the benefits of physician diversity, we have been slow to change. In 2004, 6.6% of U.S. medical students were Latino and 7.3% were African American. Today, although 16% of the U.S. population is Latino and 13% is African American, only 7.9% of medical students are Latino and 7.1% are African American. In 2008 there were 25,516 practicing EPs: 78% white and 12% URM (1474 African American, 1365 Hispanic/Latino, and 156 American Indian). In 1963, Dr. W. Montegue Cobb, in discussing the reasons for the dearth of black physicians in the country, cited “failure to become oriented toward medicine and its exacting requirements early enough.” The National Medical Association and the National Hispanic Medical Association continue to take the lead in nurturing URM high school and college students to consider medicine as a career. The Diversity Interest Group of the Society for Academic Emergency Medicine (SAEM) provides virtual and real-time advisement and support to minority students interested in EM. “Mentoring in Medicine,” an organization started by EPs, provides a pipeline program beginning at the elementary school level to encourage URM children in their desire to become health care professionals and to facilitate this desire through mentoring, tutoring, and linkage to resources.

LEADERSHIP STRATEGIES IN EMERGENCY MEDICINE

Our specialty has been a leader in both clinical care and education by raising awareness, promoting discussion, and developing strategies around diversity and cultural competency. Professional organizations, consensus conferences, and work groups have convened leaders from the broad membership of EM to develop and publish policy statements, recommendations, and tools for implementation in residency programs and clinical and academic departments.

ORGANIZATIONAL LEADERSHIP

The SAEM’s Diversity Statement asserts that “attaining diversity in emergency medicine residencies and faculty that reflect our multicultural society is a desirable and achievable goal. SAEM encourages all academic medical centers to recruit, retain, and advance a faculty reflective of the community served. SAEM encourages its members to respect, support, and embrace the existing cultural differences of its membership. SAEM encourages the development of didactic, educational, research, and other programs to assist academic emergency medicine departments to improve the diversity of their faculties and residencies.”

The American College of Emergency Physicians Policy Statement on Workforce Diversity in Health Care Settings states that “hospitals and emergency physicians should work together to promote staffing of hospitals and their emergency departments with qualified individuals who reflect the ethnic and racial diversity in our nation…. Attaining diversity with well-qualified physicians in emergency medicine residencies and faculties that reflects our multicultural society is a desirable goal.”

The American Academy of Emergency Medicine (AAEM) makes a statement on diversity within the AAEM and Emergency Nurses Association Joint Position on a Code of Professional Conduct by stating that “the ideal for emergency nurses and physicians is to practice in an optimal working environment where there is respect for diversity.”

In 2008, the Council of Residency Directors in EM convened the Promoting Diversity in Emergency Medicine Workgroup and, in 2009, published a set of primary recommendations, secondary considerations, and tools to help EM residency training programs and academic departments promote diversity.

BARRIERS AND CHALLENGES

EPs provide continuous care to patients from varying ethnic, cultural, and social backgrounds, frequently the most disadvantaged and vulnerable populations. The fast-paced and unpredictable clinical setting of the ED presents challenges that include time constraints, limited information, and inadequate resources. The health care team must establish rapport quickly and gain the trust of both patient and family. Patients who are acutely ill, sometimes with a language barrier, represent significant challenges for EPs and are at the highest risk of suffering from unconscious bias, disparities in care, and worse outcomes.

The major challenge to diversifying the physician workforce rests with the establishment of an educational pipeline, beginning in elementary school and continuing mentorship through residency training and on into faculty leadership roles. Barriers at the academic faculty level include inadequate recruitment efforts for qualified URM physicians and inadequate efforts toward retention and promotion.
and academic departments are often remiss by spending limited educational time devoted to cultural competency, which they may believe is not as important as clinical competency. Individual physicians may be resistant to acknowledging that disparities exist in their health care delivery or may be reluctant to admit to the possibility of subconscious bias.

**FUTURE DIRECTIONS**

Elimination of disparities and the development of a diverse, culturally competent workforce will require the collective effort of individual providers, EM residency programs, faculty practices, hospital administration, and medical school leadership in embracing the goals of delivering equal care to all. In closing the health care disparities gap, EM leaders and educators will play a critical role by recognizing disparity as an important issue in medicine and by developing methods of addressing the knowledge and attitudinal barriers that propagate the problem. As the population continues to become more diverse, we will need to quickly expand the professional pipeline from high school to faculty leadership positions to meet the public’s need. Development and implementation of cultural training that is compliant with the ACGME core competencies should provide our residency graduates with the skills that they need to be effective, culturally competent practitioners. Increasing workforce diversity and ensuring cultural competency are the most important strategies for eliminating racial and ethnic disparities in health care.

Introduction to Cost-Effectiveness Analysis

Emilie S. Powell and Brian W. Patterson

KEY POINTS

• Cost-effectiveness analysis (CEA) is a method for evaluating and comparing the outcomes and costs of interventions designed to improve health.
• CEA is an increasingly important component of the medical literature because it drives both clinical and policy decisions that affect the practice of emergency medicine.
• The output of any CEA model is contingent on appropriate and accurate input data.
• The primary outcome of importance in a CEA is the incremental cost-effectiveness ratio, or ICER, which represents the incremental change in cost and effectiveness when choosing one strategy over another.
• CEA model outcomes incorporate a degree of uncertainty based on input data, which is quantified in the process of sensitivity analysis.

WHAT IS COST-EFFECTIVENESS ANALYSIS?

A key skill for emergency physicians is effective integration of new interventions into existing clinical practice. Physicians have classically been trained and have become comfortable with more traditional methodologies of evaluating new interventions and treatment modalities, such as randomized controlled trials, but are often less comfortable in applying techniques such as cost-effectiveness analysis (CEA). As health care resources become more limited, costs rise, and treatment options expand, interventions and treatments are increasingly being compared and evaluated on the basis of cost.1

CEA falls under the broad umbrella of comparative effectiveness research, which refers to any study that compares the effectiveness of two or more strategies with or without regard to cost. CEA is a method for evaluating and comparing the outcomes and costs of interventions designed to improve health.2 Although many methodologies fall under the umbrella of CEA, they all share the common goal of reporting outcomes as a cost per achieving a unit of health effect (i.e., lives saved, year of life gained, quality-adjusted year of life gained). CEA tracks costs and effectiveness for a number of strategies by using both real and modeled data, compares the cost-effectiveness of the strategies, and then accounts for uncertainty in the data through sensitivity analyses.3

HOW DOES COST-EFFECTIVENESS ANALYSIS AFFECT THE EMERGENCY PHYSICIAN?

CEA is becoming an increasingly important input into health policy decisions; however, the methodology does have limitations. CEA cannot incorporate all aspects of a decision, and the results are only as good as the data available to input into the analyses. Economic analyses such as CEA cannot capture every input necessary to make health care decisions and should not be reported as scientific fact, but models and their results may be reported as aids in decision making.4 An additional criticism of CEA is that although the economic models have become increasingly complex to better represent reality, they have also become increasingly opaque to the lay reader, thus making it difficult for those without a background in economics to personally interpret the results.5 Despite these limitations, CEA offers the benefit of adding perspective to difficult questions regarding treatment choices in the setting of limited resources.5,6 If emergency physicians are to act as decision makers in our changing practice environment, it is essential to have an understanding of the basic principles of CEA.

METHODOLOGY IN COST-EFFECTIVENESS ANALYSIS

COMPONENTS OF A COST-EFFECTIVENESS ANALYSIS

CEA has four main components: inputs (costs and effectiveness and the perspective from which these variables are determined), the model, primary outcomes, and sensitivity analyses. Inputs are known values gathered from primary research, previously published literature, or estimation and are incorporated into a model. The model is the computational framework created to combine these known values along with clinical probabilities to output the overall cost-effectiveness of an intervention or set of interventions. Uncertainty in the model is evaluated and reported through sensitivity analyses.

All CEs starts with a focused clinical question that drives collection of data for analysis and allows appropriate interpretation of results. As an example for the proceeding sections, we will consider a hypothetic CEA created to answer a
clinical question. Suppose an emergency department (ED) is attempting to create a cost-effective strategy for stratification of cardiac risk in low-risk patients with chest pain. After a normal electrocardiogram and two negative cardiac enzyme tests, these low-risk patients could either be sent home or be admitted to the hospital for an exercise stress test. A CEA could be created to answer the following question: “Among low-risk patients seen in the ED with chest pain, is adding admission for an exercise stress test more cost-effective than discharging the patient directly home?”

**INPUTS**

**Perspective**

An important characteristic of any CEA is the perspective from which the analysis is conducted. The cost and effectiveness of an intervention may vary depending on the perspective. Common perspectives include those of the patient, the insurer, the employer, the hospital, or society, to name a few. For instance, from the perspective of an insurer, the cost of an intervention for a patient whom it insures is simply the amount of money paid to physicians and hospitals. However, from the perspective of an employer who provides health care insurance, the cost of an intervention additionally includes loss of productivity while the employee is ill and undergoing the intervention. The choice of perspective is of critical importance in performing and interpreting a CEA because it determines the relevance of the study for decision making.

Although one can perform a CEA from a vast number of perspectives, the most common is the societal perspective, which will be used for our example. In a CEA conducted from the societal perspective, the analyst considers all parties affected by the intervention and all costs related to the intervention, regardless of who experiences these costs and effects. Because the societal perspective includes all costs and health effects, it does not necessarily give an individual group the information necessary to make decisions on which interventions to implement. However, the societal perspective is used most commonly because it has several benefits. It is standardized and therefore allows comparison of various interventions across a broad spectrum of disciplines in medicine and society when making policy decisions. It is fair: if all decisions in health care were made from a societal standpoint, resources would be allocated to provide the most benefit to the most people. Moreover, although other perspectives may be more useful for individual groups, these perspectives do not necessarily take into account the cost or harm seen by those outside the sphere of the analyst’s perspective that the societal perspective takes into account.

**Costs**

Costs may be gathered from several different sources: institutional data, Medicare or other payment records, or elsewhere in the published literature. In our example study, the costs associated with the hospital stay, such as the cost of an exercise stress test and hospital admission, could be taken from institutional data. Because the study is conducted from a societal perspective, the true cost of these interventions to the hospital (as opposed to hospital charges) would need to be calculated. Other costs included in the study, such as the cost of a day of missed work and the cost of outpatient medical treatment of coronary artery disease (CAD), could be taken from the economic or medical literature. When evaluating a CEA, it is important to verify that the authors included all relevant costs for the stated perspective of the study and that these costs are plausible.

**Effectiveness**

In CEA, each strategy has an associated effectiveness. The effectiveness (sometimes referred to in the economic literature as utility) can be expressed with a number of different metrics. The most common measure is “life-years gained” or “lives saved.” Traditionally, most medical and public health studies use “life-years,” whereas CEAs in transportation and environmental policy use “lives saved.”

Even though life-years may be used alone as an effectiveness measure, they are generally adjusted to account for quality of life or disability. Without adjustment, two interventions would have the same effectiveness based on life-years even if one substantially increased quality of life without any extension in life expectancy. The most common adjustment unit is the quality-adjusted life-year (QALY), although other units such as disability-adjusted life-year are sometimes used.

Several methods can be used for quality-adjusting life-years to arrive at QALYs. All methods seek to find the value placed on various disease states among a group representing the interests of either a patient population or society. One commonly used method is known as the time trade-off. In a time trade-off, subjects are asked to choose between remaining in a particular health state for a fixed length of time or “trading off” that time for some shorter amount of time in perfect health. The ratio of time traded gives the QALY equivalent for the health state. For instance, if respondents would choose to equate 6 months of perfect health with 1 year in a health state, each year in that state would be worth 0.5 QALYs. Another commonly used method for quality adjustment is the standard gamble. Respondents choose between remaining in a health state or taking a gamble on a treatment that will either kill them or restore them to perfect health. If a patient in a particular health state is willing to take a 50-50 chance of dying or being restored to perfect health, that state is valued at 0.5 QALYs.

These methodologies for quality adjustment have limitations. Not all patients will value quality of life and disease states the same. The life-year-to-QALY conversion is not standard or universal, and when evaluating a CEA, one should verify that the adjustments seem appropriate. Controversy exists regarding the most appropriate derivation method, and the different approaches to derive QALYs may deliver different results even with the same respondent.

In our example model we could track the effectiveness of several outcomes. Our first outcome could be a disease-free outcome; this would represent the average quality-adjusted life span of CAD-free patients following discharge from the ED after a negative work-up. Another outcome would be a true diagnosis of CAD. Patients found to have CAD in the hospital would probably have a lower quality-adjusted life expectancy than those without CAD but would benefit from treatment of the disease. A third outcome would be patients discharged from the ED after a false-negative work-up; that is, those who have CAD but are sent home thinking that they are well. These patients would probably have the shortest life expectancy.
Clinical Probabilities
To build a model, in addition to the cost and effectiveness of the strategies, a set of clinical probabilities must be created to govern how patients flow through the model. Similar to cost and effectiveness measures, these probabilities can be derived from a number of sources, from primary institutional data to educated estimation. Our model would include population characteristics such as the prevalence of CAD, as well as test characteristics such as the sensitivity and specificity of an exercise stress test in detecting clinically relevant CAD. Anywhere a chance node lies on a decision tree, a model must contain a corresponding set of probabilities that dictate the outcomes from that node.

Discounting
An important aspect of economic analyses is the practice of discounting. Many CEAs take into account costs and health states that occur years in the future from the time of an intervention. To compare future costs and utilities with those occurring in the present, future costs and utilities are devalued at a constant yearly rate to reflect their lower opportunity cost. For example, if one needs to pay for a health intervention, clearly it is preferable to pay the same sum of money 10 years from now rather than paying today because the sum of money used for payment in the future could be invested in the meantime to generate further revenue. Therefore, a discount rate is applied to compare present and future events. The discount rate for all costs and utilities is generally approximately 3% to 5% per year in health economic analyses. Even though this value is commonly used, there is little agreement among economists regarding what represents an appropriate discount rate and exactly how this rate should be calculated.8,9

The Model
Mathematic models are used in CEA to simulate the chain of events surrounding alternative interventions so that the costs and outcomes related to the choice of one medical intervention over another can be tracked. Although it is theoretically possible to complete a CEA by measuring every variable prospectively, the broad scope of most CEAs necessitates at least some component of mathematic modeling.10,11 A successful model is transparent, internally consistent, reproduceable, and interpretable.12 Multiple modeling methodologies are used in modern CEAs; here we will cover the two most common: decision trees and Markov models. Decision trees depict decisions and chance events as branches of a tree. Computerized decision trees can track the costs and outcomes associated with various health interventions. Graphic branches in the tree represent a chain of related events, and nodes in the branches represent decisions, such as a choice between competing strategies, or chances, such as the chance of a complication developing after an intervention. Figure 218.1 depicts a simple decision tree.

Certain situations are difficult to model with decision trees alone; especially problematic are episodic or recursive disease states (i.e., a chronic disease with frequent exacerbations). For these situations more complex models, such as Markov models, are used. A Markov model consists of a set of health states, as well as allowable transitions between these states. The model moves forward with discrete steps in time; at each time step the model allows patients to transition between states along allowable transitions according to predefined transition probabilities. Markov models can be constructed independently or be inserted into decision trees. If in our example CEA we wish to model CAD in more detail and specifically include ischemic congestive heart failure states, we could use a Markov model as depicted in Figure 218.2.

Primary Outcomes
The most basic outcome from any CEA is a cost-effectiveness ratio (CE ratio), in which the cost of an intervention is placed in the numerator and the measure of effectiveness in the

---

**Fig. 218.1** Sample decision tree. The square represents a decision node, circles represent chance nodes, and triangles represent terminal nodes. Costs are tracked at each branch along the chain, and each terminal node is associated with an effectiveness. Clinical probabilities are documented below the nodes. CAD, Coronary artery disease; Pt, patient.
Cost-effectiveness frontier. The total cost of a strategy is plotted against each strategy’s effectiveness. This graph gives a representation of the additional life years gained for the additional cost of a strategy. The slope of the line connecting two points is mathematically equivalent to the incremental cost-effectiveness ratio.

Sensitivity analyses may be reported as a threshold value (i.e., a threshold value on an input beyond which the intervention is cost-effective) or continuously, in which the resultant cost-effectiveness is considered across a range of input values. A one-way sensitivity analysis is the most basic form of sensitivity analysis. It demonstrates the variability in cost-effectiveness of an intervention or group of interventions based on variation of a single input. A two-way sensitivity analysis varies two variables simultaneously to capture their interaction. Any number of parameters can be varied simultaneously, although it is challenging to graphically depict sensitivity analyses beyond two way. Figure 218.5 depicts examples of one- and two-way sensitivity analyses for our example model, as well as an example of a tornado diagram, another commonly used methodology for reporting sensitivity. Tornado diagrams give a graphic representation of the magnitude of a number of one-way sensitivity analyses simul-
The goal of multivariate sensitivity analysis is to gain a sense of model uncertainty by varying all variables simultaneously. It allows the generation of true confidence intervals of the inputs. The confidence interval for an ICER is dependent on the confidence intervals of all model inputs, as well as the structure of the model. Several methods have been described for empiric calculation of confidence intervals, but there is no consensus method. Most commonly, “bootstrap methods” are used, in which iterative methods are used to create confidence intervals from the data after the model has been run.

The most common bootstrap method for calculating multivariate sensitivity is the Monte Carlo method. In a Monte Carlo analysis, each input in a model is replaced by a distribution representing the uncertainty surrounding the input variable. For instance, in our sample decision tree we may know that the incidence of CAD in the patient population in question is 0.1, with a 95% confidence interval of 0.05 to 0.15, normally distributed. To perform a Monte Carlo sensitivity analysis, we would replace our incidence point probability with a normal distribution of probabilities with a mean of 0.1 and standard deviation of 0.025. We would perform a similar replacement for all model inputs with uncertainty. The model would then be run many times (generally at least 1000).

For each iteration of the model, the computer picks a value for each input based on the probability distribution. In the case of our CAD incidence distribution, most iterations would have values near the mean of 0.1, but some iterations would pick outlier values such that over the course of 1000 runs, the values picked would form the distribution specified. Each model run creates an individual ICER. These ICERs then form a distribution, the characteristics of which (standard deviation and confidence intervals) reflect the uncertainty of the model as whole.

Several methods can be used for reporting confidence intervals generated from multivariate sensitivity analyses. In an ICE scatterplot, individual runs of a multivariate Monte Carlo analysis are plotted as individual points on a cost-effectiveness plane. Figure 218.7 shows a sample cost-effectiveness acceptability curve in which individual model runs are compiled to form a probability distribution that reflects the likelihood that a given intervention is cost-effective at a given willingness to pay.

**EVALUATING A COST-EFFECTIVENESS ANALYSIS**

See Box 218.1 for a sample approach to critically evaluating a CEA. Though not the only approach or an all-inclusive list, it provides a framework for assessing the impact of a particular study on a clinical question. See “Suggested Readings” for more in-depth analysis.
1. What is the research question being asked?
   a. From what perspective is the analysis conducted, and is this appropriate?
   b. What population is specifically modeled or studied?
   c. Are all appropriate interventions or strategies included in the comparison?
   d. Was the choice of units describing the costs and effectiveness of the evaluated strategies appropriate?

2. What is the quality of the evidence?
   a. Are the sources of model parameter values stated clearly?
   b. Is uncertainty of the source data described (ranges given for all parameters)?
   c. Is the search strategy used to identify model data described and adequate?
   d. Were future costs and consequences discounted appropriately?

3. Is the model’s design valid?
   a. Is the structure of the model consistent with the stated research question?
   b. Are the disease states in the model driven by a sound biologic model of the underlying disease (as opposed to data available during construction of the model)?
   c. Were all important and relevant costs and consequences for each alternative identified and valued credibly?
   d. Are model assumptions clearly stated and reasonable?
   e. Is the model as transparent and reproducible as possible while adequately representing the disease and interventions studied?

4. Are the base case results presented?
   a. Are all strategies present in the base case results?
   b. Are appropriate incremental cost-effectiveness ratios calculated for all relevant comparisons?

5. Was an appropriate sensitivity analysis performed?
   a. Do the ranges of possible variable values accurately reflect the uncertainty of the data?
   b. Was a multivariate sensitivity analysis performed?
   c. Are outputs of the sensitivity analysis reported appropriately?

6. Is the model externally consistent?
   a. Are any relevant studies or models identified for comparison?
   b. Does the discussion include and address all points of concern?
Fig. 218.6 Monte-Carlo sensitivity analysis: ICE scatterplot. ICE, Incremental cost-effectiveness; QALYs, quality-adjusted life years.

Fig. 218.7 Cost-effectiveness acceptability curve. This curve displays the output of a multivariate sensitivity analysis as a function of willingness to pay. At each dollar value, the y-value of the line corresponds with the probability that the intervention is the most effective without exceeding that dollar value per effectiveness unit. QALY, Quality-adjusted life year.

Hymen

Hydroxyurea, in sickle cell disease,

Hydroxyethyl starch (HES)

Hydroxycut, toxicity of, 1340t

Hydroxychloroquine, in systemic
- dialysis in, 1403t, 1404
- diagnostic testing in, 1400b

Hyperkalemia
- in rhabdomyolysis, 1434

Hypernatremia, 1391-1396
- in neonate, 1388
- in pregnancy-related, 1017

Hyperkalemia
- in rhabdomyolysis, 1433-1434

Hyperparathyroidism, 1405-1406.
- in cancer, 1700

Hypoglycemia, 1329-1333,
- in acute coronary syndrome, 1385
- in alcohol abuse, 1380-1382

Hypophosphatemia, 1416-1417

Hypothermia, 1623.2

Hypoparathyroidism, 1405-1406.
- in cancer, 1700

Hypovolemia, 1394

Hypothermia, 1420-1423, 1421f

Hypoglycemia, 1329-1333,
- in acute coronary syndrome, 1385
- in alcohol abuse, 1380-1382
- altered mental status in, 1387-1388
- in anorexia nervosa, 1382
- in autoimmune disease, 1382
- autonomic symptoms in, 1380, 1384
- causes of, 1380-1384,
- in children, 1383-1384

Hypoglycemia
- in rhabdomyolysis, 1433-1434

Hypertension (Continued)
- in pregnancy, 1018-1019, 1022,
- in rhabdomyolysis, 1434

Hypophosphatemia, 1416-1417

Hypoparathyroidism, 1405-1406.

Hypertensive crisis, 592-601

Hypertension, 1420-1423

Hypoglycemia, 1329-1333,
- in acute coronary syndrome, 1385
- in alcohol abuse, 1380-1382
- altered mental status in, 1387-1388
- in anorexia nervosa, 1382
- in autoimmune disease, 1382
- autonomic symptoms in, 1380, 1384
- causes of, 1380-1384,
- in children, 1383-1384

Hypoglycemia
- in rhabdomyolysis, 1433-1434

Hypertension (Continued)
- in pregnancy, 1018-1019, 1022,
- in rhabdomyolysis, 1434

Hypophosphatemia, 1416-1417

Hypertension, 1420-1423

Hypoglycemia, 1329-1333,
- in acute coronary syndrome, 1385
- in alcohol abuse, 1380-1382
- altered mental status in, 1387-1388
- in anorexia nervosa, 1382
- in autoimmune disease, 1382
- autonomic symptoms in, 1380, 1384
- causes of, 1380-1384,
- in children, 1383-1384

Hypoglycemia
- in rhabdomyolysis, 1433-1434

Hypertension (Continued)
- in pregnancy, 1018-1019, 1022,
- in rhabdomyolysis, 1434

Hypophosphatemia, 1416-1417

Hypertension, 1420-1423

Hypoglycemia, 1329-1333,
- in acute coronary syndrome, 1385
- in alcohol abuse, 1380-1382
- altered mental status in, 1387-1388
- in anorexia nervosa, 1382
- in autoimmune disease, 1382
- autonomic symptoms in, 1380, 1384
- causes of, 1380-1384,
- in children, 1383-1384

Hypoglycemia
- in rhabdomyolysis, 1433-1434

INDEX
The formal definition of evidence-based medicine (EBM) is “the conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients.” This definition is useful but leaves ambiguities. What does “explicit” mean? How might we define “judicious”? What constitutes “evidence”? And perhaps most important, who is “making decisions,” the doctor or the patient?

Broadly introduced to medical culture in 1992, EBM has exploded in the past 2 decades. The term has become ubiquitous and is often co-opted by working groups, professional societies, and individual authors who neither systematically adhere to core EBM principles nor complete the fundamental tasks that define EBM. In addition, the most important principle underlying medical practice and the Hippocratic Oath—that the physician’s goals should be aligned with the patient’s goals—has not been routinely integrated into these applications of EBM.

The methodologic superstructure of EBM can be summarized by the four A’s: ask, acquire, appraise, and apply. In the text that follows we use this structure to answer clinical questions and offer a potential road map for the true, focused application of EBM. We will use two distinct, frequently encountered, high-stakes emergency department (ED) clinical scenarios—evaluation of a patient with an acute headache and evaluation of a patient with chest pain—to illustrate how physicians might use EBM to enhance their practice and knowledge and best inform and achieve their patient’s goals. Because a fully detailed demonstration of the EBM process is neither feasible nor digestible in the space provided, we will emphasize concept over detail and in many cases will be summarizing. Although we use clinical scenarios to demonstrate the EBM process, in most cases, formulation of a proper question, literature search for that question, and appraisal of the literature to help answer the question will all be done over a period of hours to days and will not be possible contemporaneously. The greatest utility of the EBM process is often in being prepared for the next encounter.

**CLINICAL SCENARIOS**

**ACUTE HEADACHE IN THE EMERGENCY DEPARTMENT**

Ms. Mason, a previously healthy 40-year-old woman, arrived at the ED 4 hours after the onset of a severe headache. It has an “acute” quality (i.e., it reached maximum intensity within minutes of onset), and she has no history of significant headaches. She appears well but is uncomfortable, with normal vital signs, a Glasgow Coma Scale (GCS) score of 15, and normal findings on neurologic examination.

Emergency physicians will immediately consider subarachnoid hemorrhage (SAH), among the most dangerous possible diagnoses, and will want to make an estimate of the probability of this disease. Had her clinical manifestations been extreme, the next step in her management would be more straightforward. For instance, consider a 50-year-old woman with a known cerebral aneurysm who goes to the ED after a sudden-onset, severe headache associated with loss of consciousness. On arrival she is vomiting and minimally responsive and has papilledema. Alternatively, consider a 25-year-old neurologically normal female with her typical migraine headache. If the primary disease that concerns us is SAH, the first patient seems very likely to have it and will be managed accordingly. The second patient, although she may have SAH, is at low-enough risk that most physicians would feel comfortable forgoing any formal diagnostic testing for the disease.

**Ask**

In contrast to the latter two cases described, Ms. Mason’s case represents true diagnostic uncertainty. She has a pretest probability (actual risk of having SAH at the moment of our encounter) that is neither immediately intuitive nor easily estimated based on clinical experience. It is in such scenarios that the medical literature is particularly useful. However, before seeking answers, we must be explicit in defining our question. We could start with a broad inquiry such as “What is the chance that she has SAH?” Formulating plus refining this question is a difficult and fundamental skill of EBM. It is an important endeavor that often has the greatest bearing on the value of the answer generated by the EBM process. Accordingly, considerable time and thought should be allocated to careful deliberation over what it is that we actually want to know. In this case, because we are primarily concerned with prognosis and diagnosis, we will focus most of our energy on defining the population most relevant to our patient.

The prevalence of SAH varies considerably across practice settings and research cohorts, which is often a reflection of biases such as spectrum bias, or enrollment of an overly narrow or broad spectrum of patients, and referral bias, which is one type of spectrum bias and typically occurs when a...
normal patients seen in the ED with an acute headache, what is the risk (or prevalence) of SAH?

**Acquire**
We begin our literature search seeking high-quality research involving patients with headache in whom SAH is a diagnostic consideration. We decide to use the free PubMed database to explore the comprehensive MEDLINE database. When searching large databases such as MEDLINE, it is generally easiest to start by combining the most general terms relevant to the question and then systematically limiting the search. Accordingly, we start with the following MeSH terms (medical subject headings, the controlled vocabulary used by the National Library of Medicine to index articles): “headache,” 52,670 results; and “subarachnoid hemorrhage,” 18,364 results. By combining the two terms with the Boolean symbol “AND,” we are left with 1224 results. To further restrict the search, we add the following limits: English, human, all adult, core clinical journals. There are 118 results remaining, a reasonable number of abstracts to review individually.

One of the first papers found is a recent publication by Perry et al.: “High Risk Clinical Characteristics for Subarachnoid Haemorrhage in Patients with Acute Headache: Prospective Cohort Study.” Scanning the abstract, we decide that it meets many of our important inclusion criteria and thus embark on the third part of the EBM process.

**Appraise**
Two major steps are involved in any critical appraisal: assessing the internal and external validity (the likelihood that study results represent truth) of the study. A few key methodologic features favor the internal validity of this paper. First, it was performed prospectively. In the context of a diagnostic study, this usually means that clinical variables are recorded in real time before the diagnosis is known by the treating physicians. In a diagnostic study using a retrospective design, physicians (and commonly consultants) recording clinical variables in the medical chart are often unblinded to the ultimate diagnosis and outcome of the patient. This can easily lead to a biased interpretation and documentation of the signs and symptoms. Second, the outcome measures were well defined. The presence of SAH was determined by testing or clinical follow-up. A positive test was either in the form of CT or abnormal findings on analysis of cerebrospinal fluid with an aneurysm evident on angiography. Because it is neither practical nor ethical to expose every patient to these commonly used

AMS, Altered mental status; HA, headache; SAH, subarachnoid headache.
criterion standard tests (the test accepted for determining the diagnosis), rigorous clinical follow-up via structured telephone interview and review of coroner office records was pursued as another way of determining patient outcomes. Third, only 1% of patients were lost to follow-up.

In terms of external validity (generalizability of the study results to our patient), there are three key features. This study was done in the ED setting. Patients were enrolled only if they had high-risk headaches: either sudden onset or associated with syncope for a duration of less than 2 weeks. Finally, they had to be alert, defined as a GCS score of 15, and were excluded if focal neurologic deficits were present.

Almost 2000 patients were enrolled, which makes this the largest and most robust data set of high-risk headache patients in an ED setting. SAH was confirmed in 130 patients, so SAH was diagnosed in 6.5% of the cohort, which translates to about a 1 in 15 risk.

**Apply**

The internal and external validity of the study results seems sufficiently strong to apply the information to our patient Ms. Mason. Taking that number to the bedside, you and the patient decide that for a potentially devastating, fatal condition such as SAH, a 1 in 15 risk is substantial and necessitates further testing. A CT scan of the head is ordered.

The patient has an uneventful course in the ED. Her CT scan is read as normal by the radiologist. You return to the patient’s bedside to have another familiar discussion.

When the diagnosis of SAH is being pursued, the current recommended approach includes a CT scan, followed by LP when imaging is negative. Based on study design and disease prevalence, the sensitivity of CT has varied widely across research populations, between 82% and 100%, and this has been judged inadequate in the context of the disease. Although a recent investigation of CT for SAH reported a sensitivity approaching 100%, spectrum bias was evident because all the subjects were referred to a neurosurgical center for evaluation.

Moving back to our appraisals step, we perform a more in-depth analysis of the study results of Perry et al. In the cohort there were 1999 subjects, and SAH was diagnosed in 130 of them. One hundred twenty-one of the 130 SAH cases were detected by CT, thus generating a sensitivity of 93%, whereas the remaining 9 cases were detected by LP. A potential limitation exists in that only 80% of the patients enrolled underwent CT and only 45% had LP performed, the criterion standard for SAH, but nearly all had extensive clinical follow-up. Because it is presumed that dangerous SAH would result in a deleterious neurologic event at some point, we decide that clinical follow-up is a good surrogate outcome (an outcome that can act as a valid replacement for the criterion or gold standard). All CT positives were considered true-positives, so we presume a specificity of 100% for the test. With this information available, we can calculate the negative likelihood ratio (LR) for a normal CT scan. The LR is a simple tool that calculates the probability of the disease based on the sensitivity and specificity of the test and the test result. In this case, with a negative CT result and 93% sensitivity and 100% specificity of CT, the calculation is 1 – sensitivity/specificity, or (1 – 0.93)/1. The negative LR in this case is therefore 0.07 (95% confidence interval, 0.04 to 0.13).

We decide to presume a worst-case scenario for the imaging test and choose an LR of 0.13, which represents the upper boundary of the confidence interval. Plotting a pretest probability of 6.5% on a Fagan nomogram and using an LR of 0.13, we generate a posttest probability of just under 1% (Fig. 1). You explain to the patient that a less than 1 in 100 chance (1 in 118 to be exact) persists that she has SAH detectable by LP. She carefully considers these numbers and asks another question: “How much lower would her risk be if LP were performed and determined to be normal?” In the EBM style of practice, one question often begets another. We return to the acquire and appraise steps.

The aforementioned literature search yields a paper by Perry et al.: “Is the Combination of Negative Computed Tomography and Negative Lumbar Puncture Result Sufficient to Rule Out Subarachnoid Hemorrhage?” In this study of

**Fig. 1** Plotting a pretest probability.
592 subjects, a subset of patients from the cohort described earlier by Perry et al., all patients with suspected SAH underwent CT and LP. Of those in whom both tests were negative, the posttest probability or risk of having SAH was 0.0001%, or 1 in a million.

You apply this information at the bedside. A negative LP finding would lower the patient’s risk for SAH from just under 1 in 100 to 1 in a million. The patient considers this information and seems conflicted. Both these risk estimates are quite low, although one clearly represents better odds. She does not want any invasive testing, however, and therefore probes further for information on the potential benefits of performing LP. She asks, “If SAH is detected by LP, what are the chances that she will benefit from that discovery?”

You reflect that this is an odd question to consider as an emergency physician. For diseases such as SAH, our goals have usually centered around detection, with a presumption of benefit to all in whom the diagnosis is made. Answering this question requires incorporating background knowledge about SAH with literature describing both the natural history of SAH and the absolute benefits associated with current neurosurgical interventions. We move to a place outside the official road map: background research involving reappraisal of the root literature. This is often an exciting place to venture and has been made more accessible by the recent efforts of many journals to electronically catalog older studies.

Any discussion of the potential benefits of detection of SAH must first start by distinguishing between aneurysmal and nonaneurysmal disease. Published case series of patients with SAH suggest that roughly 85% of cases of SAH can be attributed to leak or rupture of an aneurysm. Of the 15% that are nonaneurysmal in origin, most are classified as “perimesencephalic” bleeding events in the absence of a vascular aneurysm. Small case series suggest that patients with perimesencephalic SAH have an almost universally good prognosis. Of equal importance, no neurosurgical intervention is performed for these patients.

Applying this information, the benefits of diagnosis would probably be limited to (at the most) 85% of patients with SAH detected by LP. A patient’s post-CT risk for SAH of 1 in 118 should be modified to a 1 in 139 chance of potential benefit (1/118 x 0.85) with early detection.

This last set of figures makes another assumption: that all patients with aneurysmal SAH receive and benefit from neurosurgical intervention. However, few interventions procure a number needed to treat (NNT: the number of patients who need to be treated to achieve one good outcome) of “one.” Accordingly, it is likely that some patients, particularly those neurologically normal with SAH, will experience favorable outcomes irrespective of intervention. Ultimately, we need to know the absolute risk reduction (ARR: the absolute difference in the rate of bad outcomes between experimental and control groups) associated with neurosurgical interventions in neurologically normal patients with aneurysmal SAH to estimate the benefits of detection. The study design ideal to answer this therapy question is a randomized trial. Our search is redirected to find randomized trials comparing neurosurgery (in the form of aneurysm clipping or endovascular coiling) with no intervention in patients with SAH.

An extensive search yields several related papers reporting on the results of the Cooperative Aneurysm Study, a randomized trial of patients with intracranial aneurysms and SAH performed in the 1960s. There were four treatment arms: regulated bed rest, drug-induced hypotension with bed rest, ipsilateral common carotid artery ligation and bed rest, and intracranial surgery. As the authors of the study suggest, the group receiving regulated bed rest offered the best representation of the natural history of SAH resulting from a ruptured intracranial aneurysm.

Of the 187 patients ultimately analyzed in the bed rest group, the mortality at 6.5 years (the duration of follow-up) was 55.1%. For those classified as being in good neurologic condition, either symptom free or with minor symptoms such as headache, meningeal irritation, or diplopia, the mortality during this period was 47.4%. Most deaths were the result of aneurysm rebleeding, although some were attributed to direct effects of the initial bleeding and others to vasospasm. About 7% of the deaths were unrelated to the SAH event. To be conservative, however, we assume that half the patients with SAH who are in good neurologic condition have a reasonably good prognosis and that half will die of their disease. Thus, the potential for benefit via surgical intervention and modern therapies will be limited to about 50% of those in whom SAH is diagnosed because the others would have had good outcomes regardless of treatment.

In addition to improvements in neurosurgical interventions, medical advancements since the 1960s have resulted in many beneficial treatments for patients with SAH, including drugs such as calcium channel blockers. In one of the most recent, high-quality trials comparing endovascular treatment with standard neurosurgery, in which 88% of the patients were enrolled in good neurologic condition, 23.5% of those in the superior therapy arm, endovascular treatment, were dead or dependent at 1 year. A large, prospective observational study that enrolled more than 3500 patients with aneurysmal SAH reported similar survival data for patients initially admitted in good neurologic condition. Clearly, the contemporary cohorts fare better than patients with similar disease randomized to bed rest in the 1960s because 76% are alive with good function in some treatment groups, but it is critical to note that even with the best, most modern interventions, a substantial percentage of patients still have poor outcomes.

Accordingly, using the earlier numbers, it would seem that for neurologically normal patients in whom aneurysmal SAH is diagnosed, current neurosurgical and medical interventions are associated with a 30% ARR in mortality and poor outcome (50% to 23.5%), which translates to an NNT of about 3 (100/30). This indicates a tremendously powerful intervention inasmuch as very few modern therapies procure this likelihood of benefit.

We return to our previous calculations. The number of LPs needed to diagnose SAH was between 118 and 139. Multiplying this number by 3, we generate the number of LP tests that we would have to perform to benefit the patient with a neurosurgical procedure. This translates to a number between 354 and 417. Rounding off these numbers to facilitate communication, you explain to the patient that there is probably in the range of a 1 in 300 to 400 chance that she will be truly benefited by having LP performed.

The patient considers this information and decides to forgo the test. She understands that the disease has not been completely “ruled out” and that a negative LP would substantially lower her risk of having the disease. In the medical chart you document that an extensive discussion regarding the risks and
benefits of testing has transpired. You discharge the patient with a diagnosis of headache and tell her to return immediately should her symptoms return or any other concerning symptoms develop.

CHEST PAIN IN THE EMERGENCY DEPARTMENT

Your patient is a 45-year-old man with no previous medical history who has had less than 1 day of chest discomfort. He describes it as an aching and sometimes sharp substernal pain that has been present for 6 to 8 hours. The pain is not associated with eating or changing position, and he is “not sure” whether it is related to exertion. He denies associated cough, shortness of breath, fever, back pain, or abdominal pain. He states that he has never had this pain before and does not have any known cardiac history. He has never had a stress test or an echocardiogram.

On examination his vital signs are normal and he is generally well appearing with normal heart and lung sounds, a nontender abdomen, and no signs of peripheral edema. The electrocardiogram (ECG) that was done on his arrival at the ED shows normal sinus rhythm with no signs of ischemia or right heart strain. No old ECG is available for comparison. A chest radiograph is also obtained and shows a normal cardiac silhouette with no pneumonia, effusion, or pneumothorax.

At this point you return to speak with your patient about the findings and to discuss further management. You explain that you think it unlikely that he is having a heart attack given his normal ECG and fairly “atypical” pain. However, the patient remains concerned about the pain and asks how sure you are that his pain is not cardiac.

Background

Approximately 8 million patients seek treatment in the ED for chest pain each year, and these patients are often admitted for a work-up to rule out cardiac disease. It has been suggested that a large proportion of hospitalizations are unnecessary and that many patients undergo expensive and sometimes invasive testing. Conversely, studies also suggest that between 2.1% and 4.6% of patients with myocardial ischemia are initially discharged. Groups that seem to be at highest risk for discharge during an initial coronary manifestation are women, nonwhites, and those with a nondiagnostic initial ECG. Given the significant morbidity and mortality associated with myocardial ischemia, it is crucial that patients at risk for poor outcomes be quickly and accurately identified. The challenge for the emergency physician is in accurately stratifying risk so that patients and physicians can make clinical decisions informed by valid and relevant evidence.

In this section we discuss a subset of studies within the medical literature that deal with prognosis. These studies assess the likelihood of specific outcomes for a given patient population and can provide useful data to guide clinical decision making.

Prognosis is dependent on a number of patient characteristics, which are referred to as prognostic factors—factors that affect the outcome of the disease. These factors are not necessarily the same as risk factors, which are characteristics associated with the development of a disease. For example, in the case of our patient, gender may be considered a risk factor for heart disease, but it is not necessarily associated with a specific outcome. In contrast, the patient’s normal ECG on arrival may be considered a prognostic factor if it is found to be associated with a better overall prognosis. In the case of cardiac disease, studies show that risk factors for cardiac disease are not generally useful in identifying acute coronary syndrome (ACS), except in the case of young patients, in whom the presence of four or more of these risk factors has been associated with a significantly increased likelihood of ACS.

In the following sections we will again use the ask, acquire, appraise, and apply technique to discuss prognostic studies with a focus on the risk stratification of “low-risk” patients with chest pain.

Ask

Again, the process of formulating and articulating a clinical question that will lead to the best and most useful answer for your patient scenario is complex, and it is important to remember that we are summarizing. In the case of prognosis studies, we must properly define the most relevant study population, and we must also precisely describe the outcomes that our patient is most interested in avoiding. In this case, the patient is a 45-year-old man with no past medical history, so the studies that we look for should be those involving adult chest pain populations without significant preexisting disease. The outcomes of greatest interest to a patient seeking medical counsel for chest pain are likely to be myocardial infarction (MI) and death, both outcomes that are fairly easily defined and tracked. Thus one way to formulate our question would be, “In adult patients seen in the emergency department with chest pain and a normal ECG, what is the 30-day risk for MI or death?” Studies best able to answer this question would be those in which a cohort of adult patients with chest pain whose initial ECG was normal are monitored prospectively and rates of death and MI are recorded.

Acquire and Appraise

One option to consider, particularly when attempting to acquire evidence in an active setting of patient care (when time restraints are important), is to defer to established sources of already appraised and summarized data. One such “preappraised resource” is BestBets, a website respected by many EBM users that offers brief and simple summaries of evidence-based reviews of topics. In this case a quick BestBets search for this topic reveals an article titled “The First ECG Has Low Sensitivity for Myocardial Infarction in Patients with Chest Pain” (2000). This article examined 10 studies conducted between 1976 and 1998 that sought to assess the prognostic value of an ECG and reported sensitivities ranging from 13% to 69%. The article concluded that an initial ECG cannot be used to rule out MI. At first it seems that this review is helpful. However, on reconsideration, we realize that although information about the ECG may be generally useful, it is specific neither to our patient nor to our question, which is about prognosis. This review seems focused on the diagnostic performance (sensitivity) of a particular test (ECG).

We therefore move to performing a MEDLINE search, a fundamental skill set that is our next logical step when preappraised resources do not provide the answer. Our search, which focuses on the prognosis of patients with chest pain and low-risk features, reveals two potentially relevant and recent prospective studies. These studies distinguished between rates of MI and rates of death and had initial ECGs analyzed by physicians blinded to patient outcomes. ECGs were classified
into one of a number of groups ranging from normal to acute ST-segment elevation MI. The prospective studies quoted mortality rates lower than 1% for patients with normal ECG findings.19,24 These studies used slightly different cohorts, and the follow-up times also differed between studies. The study that is probably most relevant to our patient is the study by Forest et al., which involved 3814 adults older than 24 years who had an ECG performed for chest pain. This study found that 2% of patients with an initial normal ECG eventually suffered MI within 30 days [39 of 1912 patients], and 0.5% died [9 of 1912] (Fig. 2).

The next step in your analysis might be to ask whether the patient’s prognosis would be altered by the inclusion of cardiac enzyme testing. In this patient with a somewhat concerning description of pain and no clear diagnosis, it would be reasonable to consider cardiac enzyme testing. However, if these tests are performed and come back negative, what is the next step? Should another set of enzyme testing be performed? Can your patient go home? This is a somewhat more complicated question to test than the ECG question because there are a variety of the database of observational information from decision aid studies of chest pain to find information that is relevant and useful to our patient.

The Thrombolysis in Myocardial Infarction (TIMI) risk score has been tested in multiple populations, and most studies of chest pain patients assign a TIMI risk score to subjects. This score (see Box 1) uses seven prognostic factors, with each assigned 1 point, to create an overall risk score. The score was originally derived by using a population of patients with unstable angina or non–ST elevation MI and was used successfully to risk-stratify these patients.26 It was then externally validated in a population of patients with undifferentiated chest pain.27 Thus the score seems reproducible, valid, and applicable to a variety of populations. For these reasons, virtually all decision aid studies of patients with chest pain classify patients by TIMI risk score. Therefore we can quickly and easily calculate the TIMI risk score of our patient (it is 0) and then look at these observational data to see what the risk for MI or death was for study patients with the same risk score. Unfortunately, not all studies reported rates of MI or death separately but instead reported them in a composite outcome, including the end point, revascularization. From an EBM perspective, this last end point is problematic for two reasons.
First, a high degree of subjectivity enters into decision making about which patients undergo revascularization, and second, its utility in patients not actively experiencing an MI is dubious, thus limiting its function as a “patient-important outcome.”28 There are four studies that reported MI, death, and revascularization rates separately, two of which actually used a modified TIMI scoring system in which subjects were classified as low, moderate, or high, with low representing a score of 2 or less27,29-31 (Table 3). With approximately 1600 subjects across these studies, for patients with a TIMI risk score of 0 or low, the reported rates of MI and death at 30 days were 0% to 2% and 0% to 0.2%, respectively. For 400 subjects with a TIMI score of 0 and an alternative diagnosis per treating emergency physician, the death rate was 0.8%.29 Translating this into understandable numerical values, in patients classified as low risk by TIMI scoring, the 30-day risk for MI is lower than 1 in 50, whereas the risk for death is less than 1 in 500.

Apply
Clearly, identifying patients with “low-risk chest pain” is difficult, and many factors need to be considered, including the history and physical examination, ECG, and the results of laboratory testing. In the case of our patient, how does the evidence that we have just discussed help guide our management? The evidence suggests that although his normal ECG is certainly reassuring and helps classify him as low risk, his symptoms mean that he does have a risk for MI or death that is calculable and real. The presence of two negative sets of cardiac enzymes may further improve his prognosis (and is necessary for him to remain in the TIMI risk category of 0) but still does not reduce his risk to a zero chance for MI or death.

**BOX 1 Thrombolysis in Myocardial Infarction Risk Score**

- Age older than 65
- Known coronary artery disease
- Three or more risk factors
- ST abnormality
- Two or more anginal events in 24 hours
- Use of aspirin in the last 7 days
- Elevated cardiac enzymes
Ultimately, the data presented here are most useful for initiating an informed discussion with our patient. What level of risk is he willing to accept, and how does this relate to the level of risk you would accept? For some patients, a 1% to 2% risk for MI or death at 30 days may be acceptable because they may plan to follow up with a primary care doctor in that time who knows them well and they may dislike the prospect of an inpatient stay or work-up enough to take on some risk. Other patients, at the same risk level, may strongly desire further testing, including another set of cardiac enzymes and a potential inpatient stay. As in all aspects of medical care, clinical decisions must ultimately be based not only on knowledge and evidence but also on the expectations, desires, and values of the individual patient. As evidence-based physicians our job is to act as counsel to our patients and advocate for their interests by providing them with the information that they need to make informed, reasonable decisions. In this case we discuss with our patient the risk for MI and death and the nature and potential value of an inpatient stay and further testing. He is interested and engaged in the conversation, understands the potential risks and benefits, and decides that he would prefer to go home to his family and see his primary care physician tomorrow. We arrange the appointment for him, explain what to watch and return for, and wish him well.

CONCLUSION

Rational and informed medical decision making can happen only when physicians and patients have access to the best estimates of disease risk, testing utility, and impact of therapy. Although many clinical questions are still unanswerable, the medical literature is replete with information that can provide sound guidance in patient care. Practicing EBM, which means learning how to ask a well-defined clinical question, acquire relevant high-quality studies, and understand the basic tenets of critical appraisal and how to apply clinical research results at the bedside, moves us one step closer to practicing an art with a true foundation in science.

Basic Emergency Ultrasound
Christine Butts

KEY POINTS

- Emergency ultrasound is frequently used by emergency medical providers for the management of patients in the emergency department for a variety of indications.
- Emergency ultrasound focuses on answering a specific question that has an impact on patient care.
- Applications for emergency ultrasound are expanding rapidly and having a positive impact on patient care.

INTRODUCTION

The use of ultrasound in emergency medicine, also known as bedside ultrasound or emergency ultrasound (EUS), has grown rapidly over the past 10 to 15 years. What began primarily as an adjunct for the evaluation of trauma patients has expanded to provide a use for the evaluation of almost every organ system. Ultrasound, previously thought of as the domain of radiologists, is now used by faculty physicians, residents, medical students, and even nursing staff in the emergency department (ED) for the day-to-day evaluation and management of patients. EUS also has a place outside the ED, and its role in international and disaster medicine continues to be defined.

Distinction must be made between EUS and ultrasound performed by other specialties. The American College of Emergency Physicians (ACEP) has defined EUS as “the medical use of ultrasound for the bedside diagnostic evaluation of emergency medical conditions and diagnoses, resuscitation of the acutely ill, critically ill or injured, guidance of high risk or difficult procedures, monitoring of certain pathologic states and as an adjunct to therapy.” EUS is performed or directly supervised by emergency physicians in a variety of settings. Importantly, EUS is primarily distinguished from consultant-performed ultrasound in that it is a goal-directed, focused ultrasound examination. In short, EUS seeks to answer a brief or “yes or no” question. For example, in a patient with a complaint of abdominal pain and a positive urine pregnancy test, EUS seeks to answer the question “Is an intrauterine pregnancy present?” to guide diagnosis and treatment of the patient. Ultrasound performed by a consultant answers the question in a more expansive manner. For example, in the aforementioned patient, ultrasound performed by radiology or obstetrics and gynecology seeks to evaluate all the organs of the pelvis and to describe any abnormalities identified.

WHAT WE ARE LOOKING FOR

The most common uses for EUS are listed in Box 1. Additionally, the ACEP released the Emergency Ultrasound Imaging Criteria Compendium in 2006, which further elucidates and defines the indications, technique, and interpretation of each of the eight primary types of bedside ultrasound. Although this list is extensive, applications for EUS continue to be refined and grow as emergency physicians respond to the challenges of patient care.

PHYSICS OF ULTRASOUND

In its most basic terms, ultrasound uses sound waves with a frequency of between 2 and 20 megahertz (MHz). Crystals in the ultrasound transducer are affected by electrical energy, in a process known as the piezoelectric effect, and emit sound waves at varying frequencies. These sound waves then travel into the body and are reflected (or echoed) back to the transducer with varying speed and strength. Based on these characteristics of return, the ultrasound transducer is able to determine the characteristics of the tissues being scanned.

Tissues that are similar to water transmit sound waves very well and reflect less sound back to the transducer. Examples of these types of tissue in the body are the bladder, blood within the arteries and veins, and the vitreous humor of the eye. These tissues are seen as black or anechoic (without echoes) on the screen (Fig. 1). Conversely, tissue that has less water and is more dense reflects most or all of the sound waves that strike it. Examples of these types of tissue in the body are bones, tendons, and gallstones. These tissues are seen as white or hyperechoic (a lot of echoes) on the screen (Fig. 2). Continuing this logic, all other tissues that are somewhere in the middle of these textures fall into the range of shades of gray (Fig. 3). Objects that are mostly solid but contain some water are a lighter shade of gray, whereas objects that contain more water but are somewhat solid are a darker shade of gray.
Modifiers of echogenicity are used frequently, especially to compare one object with another. For example, one object may be described as more echogenic (creating more echoes) than surrounding objects. It may also be described as hyper-echoic with respect to surrounding tissues. Two tissues that are similar in nature are described as being isoechoic (the same amount of echoes) with respect to each other.

**SELECTING A TRANSDUCER**

The type of transducer selected determines which frequencies are available to evaluate the tissue chosen. When attempting to select a transducer, it is helpful to think of the goals of your examination. Transducers are broadly divided into two types: high frequency and low frequency. High-frequency transducers allow excellent resolution but are limited in depth of penetration (Fig. 4). Evaluation of soft tissue for a foreign body or abscess is an example of the type of bedside ultrasound that would be best with a high-frequency transducer. Conversely, low-frequency transducers allow greater depth of penetration but do not provide as much resolution (Fig. 5). Evaluation of the abdominal aorta or the gallbladder is an example of the type of bedside ultrasound that would be best with a low-frequency transducer. Within each class there are multiple types of transducers distinguished by the shape of the transducer and the way that the sound waves are propagated.

**IMAGE ORIENTATION**

Orientation is frequently the most difficult task for beginning sonographers. Each transducer has a dot or line on one side, known as an indicator (Fig. 6). This indicator corresponds to a dot or mark on the screen, which is typically on the left side of the screen (Fig. 7). By convention, when performing ultrasonography, the indicator is typically pointed toward the patient’s right side or toward the patient’s head. Echocardiography is an exception and its orientation is discussed further in Chapter 5. When the indicator is pointed toward the patient’s right, a transverse image is obtained, similar to that obtained with a computed tomography scan (Fig. 8). In this type of image, objects on the right side of the screen are on the left side of the image.
Fig. 4 Example of an image of an abscess taken with a high-frequency transducer.

Fig. 5 Example of an image of the aorta and inferior vena cava taken with a low-frequency transducer.

Fig. 6 The indicator on a phased-array transducer, highlighted by the arrow.

Fig. 7 The indicator on the screen (arrow), which corresponds to the indicator on the transducer.

Fig. 8 Transverse image of the epigastric area.

Fig. 9 Side of the patient’s body and objects on the left side of the screen are on the patient’s right side. Objects closer to the top of the screen are closer to the surface and objects at the bottom of the screen are deeper within the body. When the indicator is pointed toward the patient’s head, a sagittal or coronal image is obtained (Fig. 10). In this type of image, objects on the left side of the screen are closer to the patient’s head (more superior) and objects on the right side of the screen are closer to the patient’s feet (more inferior). As just noted, objects at the top of the screen are closer to the surface and objects at the bottom of the screen are deeper within the body (Fig. 11).

IMAGE MANIPULATION AND ARTIFACTS

Adjusting the image to achieve the best image possible can be challenging and requires a knowledge of artifacts and the tools available that adjust the image.
Once an image has been obtained, the depth of the screen should be adjusted to focus on the area of interest (Fig. 12). Most ultrasound machines have a depth knob or set of buttons. Selecting too great a depth prevents the sonographer from achieving the best possible magnification and resolution of the area of interest (Fig. 13). Selecting too shallow a depth may prevent the sonographer from viewing the entire area of interest and result in missing important details (Fig. 14).

The gain button is another setting that is frequently manipulated. Increasing the gain increases the strength of the echoes returning to the transducer. This makes the image appear brighter. It should be noted that increasing the gain will not improve the overall clarity of an image (Figs. 15 and 16). Gain can be thought of as the volume knob on a radio. When the radio is set between stations, you will hear some static with some music. Turning the volume higher will increase the
Fig. 14  Example of too little depth. At the bottom the screen the inferior vena cava is partially cut off, thereby limiting the ability of the sonographer to evaluate the entire area fully.

Fig. 15  Image demonstrating overuse of gain.

Fig. 16  Image demonstrating correct use of gain.

Fig. 17  Example of acoustic shadowing as caused by the ribs. A dark black line can be seen emanating from the ribs (arrow).

Fig. 18  Example of acoustic shadowing caused by gallstones. A dark black line can be seen emanating from the gallstones (arrow).

sound of the music but will also increase the sound of the static. This is analogous to increasing the gain on a poor-quality image, a common mistake made by beginning sonographers. The best possible image should be obtained before attempting to increase the gain.

When performing ultrasonography, artifacts are encountered frequently. They are primarily frustrating to the ultrasonographer but can be helpful in certain circumstances.

One of the most frequently encountered artifacts is acoustic shadowing. When the ultrasound wave strikes a hyperechoic object, it is reflected strongly and sends almost all of its energy back to the transducer. The transducer recognizes that there is a dense, hyperechoic object present but is unable to define the objects directly behind it because few sound waves pass through the object. This results in a strong black vertical line, or shadow, extending deep to the white, hyperechoic object. This artifact can be a hindrance, such as when ribs create shadows and impede views of the chest and abdomen (Fig. 17). Shadowing can also be helpful in identifying abnormalities, such as gallstones or foreign bodies (Fig. 18).
The presence of air creates several artifacts that may frustrate the sonographer. In general, ultrasound waves do not interact well with air. Air causes the waves to scatter, which results in a hazy, gray appearance that obscures underlying objects. Another type of artifact produced by air, a “dirty shadow,” might be produced by the interface of the sound wave with gas (Fig. 19). This type of shadowing is grainier and more irregular than that seen with the “clean shadowing” described earlier.

An artifact that frequently proves helpful to the sonographer is acoustic enhancement, which occurs when the ultrasound waves encounter a fluid-filled structure. Such structures, as with water, conduct sound waves very well with little loss of energy. More ultrasonic energy is available when the sound reaches the object on the other side of the fluid. This results in a brighter, clearer image immediately behind the fluid-filled object. An example of this effect is ensuring a full bladder before performing a transabdominal scan of the pelvis (Fig. 20). The bladder acts to enhance the sound wave, thereby providing a clearer image of the uterus and adnexa.

### OTHER ULTRASOUND MODES

B-mode ultrasound, in which returning echoes are plotted on screen as an image, is the format with which most sonographers are familiar. A-mode is an infrequently used mode that plots only the amplitude of returning echoes as a series of lines.

M-mode ultrasound is used to evaluate objects that are in motion and is most frequently used by beginning sonographers to evaluate fetal heart tones. More advanced sonographers may use M-mode to evaluate the valves of the heart or the inferior vena cava. M-mode allows the sonographer to evaluate the typical ultrasound image simultaneously with a distinctive waveform. This waveform represents time on the horizontal axis and movement of objects on the screen on the vertical axis. When an object moves toward the transducer, it is represented by an upward deflection. When an object moves away from the transducer, it is represented by a downward deflection. The up and down movement of an object (e.g., a fetal heart valve) causes a sinusoidal waveform (Fig. 21).

D-mode, or Doppler, relies on the phenomenon of the Doppler or frequency shift to evaluate objects that are moving as they are imaged (e.g., blood within an artery). Spectral Doppler uses this frequency shift to generate a continuous waveform that can be used to glean information about the object in question. For example, the speed of blood flow across a valve can be calculated with spectral Doppler (Fig. 22). Color Doppler simplifies the Doppler signal and assigns color (typically red or blue) to an object in motion to indicate the direction of movement (typically toward or away from the transducer) (Fig. 23). This mode is also frequently used by...
sonographers to identify sources of blood flow, such as to identify the pulsatile quality of an artery. Finally, power Doppler assigns only one color to indicate the presence of blood flow but has increased sensitivity. This mode is ideal for detecting blood flow within low-flow states, where traditional color Doppler may not be sensitive enough to detect flow.

Fig. 22 Example of the waveform created by use of spectral Doppler to evaluate flow across the tricuspid valve.

Fig. 23 Example of the use of color Doppler to evaluate flow in the femoral artery and vein.

Conflict Resolution in Emergency Medicine

Gus M. Garmel

KEY POINTS

- Conflict is the result of discordant expectations, goals, needs, agendas, communication styles, and backgrounds between individuals. At least two perspectives contribute to conflict.
- Conflict in emergency medicine may occur with patients, family members, nurses, consultants, residents, students, hospital administrative staff, or agents inside and outside the emergency department.
- The goals of effective conflict resolution are to optimize immediate outcomes and establish a solid foundation for subsequent interactions. Success depends on one’s communication style, awareness of other’s needs and psyche, and understanding of the dynamics of relationships.
- Successful conflict resolution requires a systematic and structured approach. It is important to recognize each participant’s principal interests and underlying positions. Having a strong best alternative to a negotiated agreement is beneficial. Possessing a “win-lose” attitude interferes with successful conflict resolution.
- Not all conflict in emergency medicine can be resolved immediately, if at all; some resolutions require the assistance of a neutral third party, such as a mediator. This is especially true for emotionally charged topics, differences in values, or differences occurring between individuals having unequal power.
- Efforts to prevent conflict before it happens are recommended whenever possible.

The problem with conflict is not its existence, but rather its management.¹

Conflict is inevitable. Opportunities for conflict in emergency medicine (EM) are numerous because individuals with different backgrounds and divergent agendas interact over important concerns (e.g., patient care or resource utilization). By nature, these interactions take place under time constraints, which often exacerbates conflict. Many interactions between emergency physicians (EPs) and patients, family members, and staff or consultants occur with limited or no previous working relationship or when previous interactions have been problematic. As a result, the parties involved may be unable to reflect on previous successful interactions, which often decreases the likelihood of intense exchange.²

Controversy exists about the value of conflict. Many believe that at its best, conflict is disruptive. Most agree that at its worst, conflict is destructive to team harmony and patient outcomes. However, conflict also serves as a creative force by providing both initiative and incentive to solve problems.

This online version of the published chapter describes conflict in general and in detail, suggests many of its causes, and identifies contributing factors. Several examples of conflict specific to EM are discussed. The importance of effective communication in conflict resolution is presented, as well as its role in deescalating, minimizing, and preventing conflict. Recommendations for decreasing conflict are offered, and EPs are guided through the challenges of conflict resolution. The ultimate benefits to the patient, staff, and EP of resolving conflict are described, including optimizing patient care, decreasing patient morbidity, and maximizing an individual’s or health care team’s overall satisfaction. Finally, several strategies to facilitate conflict resolution are reviewed.

Communication, in the form of language and interaction, and power, in terms of how conflict is managed (or mismanaged), are tremendously important in the dynamics of groups. EM is very much about group dynamics because physicians, nurses, and other staff members must consistently demonstrate successful teamwork to offer patients the best possible outcomes. Louise B. Andrew, MD, JD, stated that “… conflict is often the result of miscommunication, and may be ‘fueled’ by ineffective communication.”³

Three important sources of conflict have been identified: resources, psychologic needs of individuals or groups, and values. Resource-based conflicts relate to limited resources, common in EM. The premise here resulting in conflict is “I want what you have.” Psychologic needs include power, control, self-esteem, and acceptance. These needs often exist under the conflict’s surface and can be difficult to identify or address. Values (beliefs) are fundamental to conflict. Core values (e.g., religious, ethical, financial) or those involving patient care are difficult to change and therefore generally assume a large role in conflict. Differences in values among people or groups (e.g., health care professionals and physicians with different training) may result in repeated conflicts. The expectations that EPs have of hospital and emergency
Intimidation clearly affects patients’ safety and that gender made little difference. However, not all conflict in medicine is the result of intimidation. The ED environment is particularly predisposed to conflict, and conflict occurs for many reasons. Differences in professional opinion and value systems among staff members and patients are only a few of the contributing factors. EPs must interact with individuals from all areas of health care, at all times of the day and night, and during periods of great stress. The result is often tension and conflict. Depending on the size of the hospital or medical staff and the amount of turnover among health care personnel, EPs are not likely to know all the individuals with whom they must interact. This challenges EPs because they are not familiar with each medical staff member’s idiosyncrasies, preferred practice patterns, or communication style. These interactions create even greater difficulties for new EPs lacking a history of a favorable reputation or successful relationship with hospital staff and significantly increase the likelihood of conflict.

Conflict in EM results from a mismatch of expectations between patients, family members, and providers or consultants, as well between nurses, ED staff, and ancillary staff outside the ED. Patients and family members may have unrealistic expectations about their ED experience, not to mention the pain or fear that brought them to the ED. Nurses may have unrealistic expectations of physicians, especially those whom they do not know, and all participants may have widely differing cultural backgrounds. Although gender representation of EPs has become more equal, older EPs tend to be male, whereas nurses are predominantly female. John Grey’s bestselling book *Men Are from Mars, Women Are from Venus* (HarperCollins, 1992) comments on the frequency of misunderstandings and communication difficulties that exist between genders. Misunderstandings and communication problems exist in the workplace between age groups, known as generational cohorts. Consultants may easily be frustrated with the ED staff, often based on previous unsatisfying experiences. Additionally, each time that consultants are contacted, their practice, social life, or sleep is disrupted. This increase in workload might be enough to ignite conflict.

Numerous additional factors further explain the high likelihood of conflict in EM. Diversity in training, experience, and perspective often results in differences of opinion between EPs and colleagues from other areas of medicine, including nursing. For example, conflict arises simply from the fact that EPs do not want to send someone home who should not go home, whereas hospital-based physicians or specialists may prefer to not admit patients (or be pressured not to) who do not require admission. These two opposing “forces” create conflict.

The responsibility of patient advocacy assumed by EPs and ED staff often creates conflict because it may not coincide with the interests of the patient or family members. If a patient’s decision-making capacity is impaired or their legal advocate is not present, EPs have the duty to act in the best interest of the patient, state, or society regardless of the patient’s wishes. One common challenge occurs when a patient with a history of substance abuse and chemical
dependency demands narcotics for “pain.” An EP’s refusal to prescribe narcotics is certain to create conflict. Conflict also occurs when a patient or family member desires admission to the hospital without medical justification or desires consultation with a specialist that is medically unnecessary or inappropriate at that time. Other times an EP may believe that it is in the patient’s best interest to be admitted to an inpatient medical service even if hospitalization may not influence the ultimate outcome, which creates conflict with the admitting service. Conflict may also develop between two services over which service will admit a patient. The EP must mediate this dispute by keeping the patient’s needs and interests at the forefront of the discussion.

Other aspects of EM that predispose to conflict include issues regarding diagnostic testing. Certain tests may have restricted periods of availability. Conflict is inherent when a necessary test available at one period of the day is no longer available despite the full-service expectation of emergency care. Patients (and EPs) are frustrated by this situation and often take out their frustrations on EPs and the ED. Even specialty consultative services are frustrated at these limitations despite their own limited availability for providing patient care. Many tests may not be indicated or may even be harmful to patients. If patients want these tests, conflict is inevitable if the EP serves in the role of patient advocacy while simultaneously serving society’s needs of managing with limited resources.

Perhaps the area most likely to create conflict is ineffective or incomplete communication between two or more parties. Given the cultural and language differences between patients, families, nurses, staff, and consultants, communication challenges prime the ED for conflict. Frustration, unmet expectations, time constraints, and limited staff, equipment, space, and privacy may be overwhelming if communication is suboptimal or barriers to effective communication exist.

Because the specialty of EM is so complex and has tremendous liability associated with its practice environment, many areas of potential conflict have been addressed at the federal, state, and local levels. Common sources of conflict include the patient care responsibilities of on-call consultants, minimum time standards for patients to be admitted and for hospital-based providers to see admitted patients, patient transfers to or from outside hospitals, telephone treatment of private patients who go to the ED, and use of the ED for directly admitting patients or performing various procedures. Hospitals have established guidelines addressing these issues in an attempt to prevent conflict before it occurs. Despite these policies, conflict still occurs. Frequently, these issues result in troublesome outcomes for patients, staff, and hospitals and thereby generate unwanted public attention. EM organizations are addressing these and other areas of potential conflict based on the needs of emergency patients and professionals. As health policy and the specialty of EM evolve, new challenges will be identified with more issues requiring resolution (Box 3).

As the specialty of EM has gained popularity since the 1980s, hospital administrators and medical staff members have increasingly come to recognize the importance of the role of the ED and EPs in delivery of health care. Multiple factors are responsible, such as mandatory exposure to EM in medical school, greater public awareness of our specialty, well-conducted outcomes research regarding EM, and popular television series that represent our specialty in a positive light. Talented medical students from each class are now entering the specialty, and consequently the new generation of primary care physicians and specialty consultants have relationships with members of our profession. Furthermore, many challenging situations that result from the nature of EM practice are less likely to create conflict than in previous decades because hospital administrators seem more willing to collaborate with ED leadership to prevent conflict before it occurs. Many EM leaders are sharpening their administrative skills to allow them greater success when exchanging ideas with hospital leaders. Opportunities for communication, education, and problem solving in areas prone to conflict, especially during “business hours,” is in the best interest of patients and the entire medical staff.

### THE IMPORTANCE OF COMMUNICATION

Effective communication is extremely important to the process of conflict resolution. For effective communication to occur, mutual respect and concern must exist between parties, including respect for an individual’s professional and personal choices. Many physicians have difficulty interacting with individuals who do not share similar values, such as work ethic, practice style, or lifestyle. Physicians have often witnessed
and learned attitudes, communication patterns, and styles of interaction with staff from mentors, role models, or other authority figures dating back to medical school or training.8 Communication is difficult for various reasons, especially because many physicians are poor listeners. Physicians interrupt patients early and often; these patterns are probably present during communication with colleagues and team members, particularly during stressful situations. In the ED, time constraints make communication challenging, although this style of communication may be necessary in high-acuity situations. Communication is also challenged by the fact that it commonly takes place in a public area. When done by telephone or electronically, visual cues are eliminated, thus making communication even more prone to misunderstanding or conflict. Furthermore, individuals may have unique or different agendas, which makes it even more difficult to communicate efficiently let alone effectively. Past interactions have an impact on future communications—previous negative interactions are far more likely to be remembered than positive ones. The personalities of different specialists often clash, thereby contributing to the likelihood of conflict.

Communication skills of physicians are not always developed with these concepts in mind. The Model of the Clinical Practice of EM, originally published in 2001 and most recently updated in 2009, includes an administrative section on communication and interpersonal issues that lists conflict resolution as an important subheading.9 This model was jointly approved by the American Board of Emergency Medicine, American College of Emergency Physicians, Council of Emergency Medicine Residency Directors, Emergency Medicine Residents Association, Residency Review Committee for Emergency Medicine, and Society for Academic Emergency Medicine. Another publication by leaders in EM has similarly described the importance of integrating communication and interpersonal skills as defined by the Accreditation Council for Graduate Medical Education core competencies to educate EM residents.10 These documents guiding the training of future EPs emphasize the importance of acquiring and mastering these essential skills.

A thorough three-part series of articles that focused on physician-patient communication in EM shared many pearls and problems inherent to our practice.11-13 Other excellent references describe the importance of the physician-patient relationship and EP communication.14,15 The Association of American Medical Colleges, for instance, included communication in medicine as a central aspect of its Medical Schools Outcomes Project, which is intended to guide curricula in all U.S. medical schools. In 2004 the National Board of Medical Examiners began requiring all U.S. medical students to be evaluated in terms of their communication skills, as well as their clinical skills. The Accreditation Council for Graduate Medical Education now requires all U.S. residency programs to provide instruction in interpersonal and communication skills.16 Medical licensing bodies have identified the importance of physician communication. As a result, instruction in this area (and that of conflict resolution) is now required in EM training programs.

In clinical practice, physicians characteristically spend much of their time listening and responding to patients’ concerns. Studies have consistently found that clinicians’ interpersonal skills are not always as good as patients or nurses desire. Research has demonstrated that poor communication skills and the lack of team collegiality and trust lead to lower patient satisfaction and worse patient outcomes.17 Interestingly, when physicians and critical care nurses were surveyed to examine such behavior, nearly all physicians did not consider their collaboration or communication with nurses to be problematic, whereas only 33% of nurse respondents rated the quality of this behavior high or very high.18

Interacting with consultants is equally challenging in terms of communication and other areas likely to result in conflict. A multicenter survey from London of 171 newly appointed senior house officers demonstrated the frequency and importance of communication problems, especially with reference to consultations in the ED. These authors concluded that senior house officers serving in EDs could benefit from training in consultation skills in which communication skills are taught.19 It is not clear from this article how much communication training these individuals had before taking on their roles as senior house officers or how much or what type of training they would require. The challenges of interacting with consultants and the difficulty evaluating these interactions are described throughout the EM literature.20,21

A new era of patient care and physician training has developed. These changes are in part a response to the call by several medical organizations for improved training and competence in the communication skills of physicians. The Patient’s Bill of Rights, resident work hour (duty) restrictions, and the Institute of Medicine’s “Report on Medical Error” released in 1999 all raised awareness of the importance of physician communication, interpersonal skills, and effective team functioning to improve patient safety. Though difficult to study, it will be interesting to see whether patient care outcomes and satisfaction within the medical profession improve over time as a result of these changes.

Many issues challenge communication in EM. Time urgency seems to be ubiquitous to all communication in the ED, yet many physicians and health care professionals are unaccustomed to this challenge. Difficulties with challenging patients and the uncertainty of high-risk situations make simple communication in the ED even more difficult. Multiple distractions, frequent interruptions, background noise, concerns about other patients, and frustrations with the ED or the consultation process often result in fractured communication. This situation is likely to create strain in the relationships of colleagues and consultants over time, if not immediately. Therefore, an established communication style and rules (when possible) for unavoidable consultations are integral to smooth operation of the ED.

Rosenzweig defined emergency rapport as a “working alliance between two people,” including recognizing each other’s needs, sharing information, and setting common goals. He went on to write “…rapport implies mutuality, collaboration, and respect, and is built upon a groundwork of words and actions.”24 Although the rapport that Rosenzweig referred to describes physician-patient interactions, it can just as easily (and perhaps more importantly) be used to describe interactions between physician colleagues or health care workers.

Finally, the role that stress has on physician communication must not be overlooked. Besides patient care stressors, it is stressful for EPs to contact physicians about patient care issues, particularly at night.22 It is especially difficult for EPs to contact physicians with hospital leadership roles, with reputations for demeaning behavior, or in senior positions that may
affect partnership opportunities or future employment. These situations may directly or indirectly result in less than optimal patient care when an EP’s desire to avoid conflict takes priority. Fortunately, instruction in communication and conflict resolution is required not only in EM training programs and medical schools but also by many other residency programs.

**COSTS OF CONFLICT**

With these issues in mind, what are the costs associated with conflict in EM? Staff morale is likely to be low in EDs with high levels of conflict. Staff turnover and dissatisfaction with the work environment are likely to be high. Management will probably need to address an increasing number of complaints about the ED from it and other areas of the hospital, which takes up valuable administrative time. Conflict interferes with patient satisfaction, throughput, quality of care, and safety. Pride in the ED may decline, thus further reducing morale and creating a potentially debilitating negative spiral.

Research has also shown other costs of conflict. In 1986, Knaus et al. demonstrated that predicted and observed patient death rates appeared to be related to the interaction and communication among physicians and nurses. In this prospective study from intensive care units at 13 tertiary care medical centers, controlled for APACHE II (Acute Physiology and Chronic Health Evaluation II) scores, patient mortality appeared to be related to the degree of intergroup conflict. The authors concluded that the “degree of coordination of intensive care significantly influences its effectiveness.” Interpersonal or intergroup conflicts also probably result in decreased patient safety. In the Conflicus study, a survey supported by the European Society of Critical Care Medicine, the authors recorded the prevalence, characteristics, and risk factors for conflict in intensive care units in 24 countries. More than 70% of the respondents perceived conflicts. The most common types of behavior responsible for conflict were personal animosity, mistrust, and communication problems. These conflicts, perceived as severe by more than half, resulted in job strain in those participating in the study.

The impact that conflict (and poor conflict resolution) has on EPs and ED staff members is significant. In addition to increasing the likelihood that the ED will be an unpleasant place to work, increased stress and decreased job security for the EP and staff are possible. Reduced physician reimbursement with respect to peers may result and cause even greater professional dissatisfaction. These conditions may lead to isolation, withdrawal, or depression. Substance abuse and alcohol or chemical dependency are possible, as are marital strife and family or other personal difficulties in physicians who repeatedly generate conflict with others. Not all stress is perceived or experienced in a similar manner. This is particularly true if staff members are of different gender, culture, training, and generations. Medical errors are likely to occur more frequently, a situation that may compromise patient care and worsen patient care outcomes. Patients are likely to identify conflict among staff members, which may lower patient satisfaction. The emotional and financial costs to patients, staff members (especially nurses), consultants, managers, and administrators are immeasurable if an EP frequently creates conflict and does not possess the skills to identify his or her contribution, minimize it, or resolve it promptly.

**CONFLICT RESOLUTION IN EMERGENCY MEDICINE**

If conflict is a disruptive yet inevitable force in EM, conflict resolution and the skills necessary to achieve it are key factors for favorable patient care. Conflict management starts with effective communication between parties. Successful conflict resolution therefore requires parties to demonstrate a willingness to listen fully to the concerns of each other without interrupting or planning a reply. Expressing a willingness to find common ground may help resolve conflict or at least deescalate it. A healthy approach to conflict resolution includes treating the other person with respect, actively listening (e.g., paraphrasing, demonstrating understanding), and clarifying your own needs and perspective.

Conflict resolution has been defined in many ways, but each definition comments on the importance of the present interaction and its impact on subsequent interactions during inevitable future conflict. The 2005 Nobel Prize in Economic Sciences was awarded to two researchers of game theory (a branch of applied mathematics) and its role in studying interactions and managing conflict among groups or people. This theory states that the actions of one party in a conflict affect its adversary’s subsequent behavior. John Nash (the subject of A Beautiful Mind) and two other scholars brought public awareness to the concept of game theory when they received the Nobel Prize in Economics in 1994.

Individuals, groups, and organizations respond to conflict in many ways (Fig. 1). Response styles are generally witnessed (or learned) types of behavior from parents, childhood contacts, mentors, and role models. In other words, an individual’s approach to managing conflict is likely to be adopted as a dominant, often long-term approach that has generally worked for that individual (yet may not work from other people’s perspective). Difficulties in handling conflict may result in unhappiness or lack of success, as well as repeated problematic interactions with staff members and colleagues.

![Fig. 1 Preferred pathway of conflict resolution.](Adapted from Ahuja J, Marshall P. Conflict in the emergency department: retreat in order to advance. Can J Emerg Med 2003;5:429-33.)
It is relatively easy to recognize that the conflict itself is not necessarily problematic but that the manner in which individuals (or organizations) deal with it may be. Thomas and Kilmann offered a matrix illustrating five distinct responses to conflict that vary along the axes of assertiveness (the extent to which individuals attempt to satisfy their own concerns) and cooperativeness (the extent to which individuals attempt to satisfy the other person’s concerns). (Adapted from Thomas-Kilmann Conflict Mode Instrument. Available at www.acer.edu.au/publications/acerpress/onlinetesting/documents/TKI.pdf.)

Each of these methods for dealing with conflict has situations that may be effective. The avoiding style uses the premise “I leave and you win” or “I’ll think about it tomorrow.” The goal in this style is to walk away or delay. This style is characterized by low assertiveness and low cooperativeness. Neither party’s concerns are met when this style of conflict resolution is used.

In the accommodating style, one party lets the other win (“It would be my pleasure” is the extreme). This style is characterized by low assertiveness and high cooperativeness and can be either an act of selflessness or one of obeying orders. The goal of this method is to yield or give in, typically by ignoring or neglecting one’s own concerns to accommodate those of the other party. It may be useful for issues of little importance or for creating good will and demonstrating reasonableness. Unfortunately, the accommodator can accumulate ill will if this style becomes dominant and is abused by others. In the extreme, this style may result in poor patient outcomes.

In the compromising style of conflict resolution, both parties “win some and lose some.” Made famous by television personality Monty Hall, “Let’s make a deal” best describes this style. This method has moderate assertiveness and cooperativeness and involves negotiating or splitting any differences of opinion. The goal is to find some middle ground (often expeditiously) and to exchange concessions, unlike the more time-consuming style of collaborating. The compromising method may be helpful in issues of moderate importance, especially when time constraints exist.

In the competing style, a conquest within the contest is the goal of the competitors. This style results in someone winning and someone losing (“My way or the highway”). High assertiveness and little cooperativeness dominate this interaction. This style may have utility when making unpopular decisions, especially for a leader or manager. It tends to create quick results and is often used when bargaining is not an option or the position that one supports is undeniably correct. This style is, however, one-sided and likely to be unpopular with others.

The collaborating style is the most complex style of conflict resolution and yet is the method to adopt whenever possible. Its outcome generally causes both sides to win. Collaboration is one of the main tenets of “win-win” negotiations and involves the philosophy that “two heads are better than one.” Characterized by high assertiveness and high cooperativeness, this style is best used for learning, integrating solutions, and merging perspectives. Digging into the issues, exploring them in depth, and confronting differences are components of this method to manage conflict. This style often results in increased commitment and improved relationships among the involved parties.

The distinct advantages of using the collaborating approach are that relationships are preserved for future interactions and substantive outcomes may be achieved. This approach to dealing with conflict is the most challenging and perhaps takes the longest to negotiate. Consequently, the collaborating approach may be difficult in the time-pressured setting of the ED. However, ideal outcomes can be obtained if the willingness and the resources exist to pursue the collaborative method.

The book Gandhi’s Way: A Handbook of Conflict Resolution examines the principles of moral action and conflict resolution, with the goal of finding satisfying and beneficial resolutions to all involved. Gandhi used the term satyagraha, which means “grasping onto principles” or “truth force.” The basic premise of Gandhi’s approach to conflict is to redirect the focus of a fight from persons to principles. He assumed that behind any struggle lies a deeper clash, a confrontation between two views that were each in some measure true. Every fight, according to Gandhi, was on some level a fight between differing “angles of vision” illuminating the same truth.

A contemporary phrase used when dealing with two perspectives is that “the truth lies somewhere in the middle.” Considering this concept, it is relatively easy to see why conflict is so prevalent in society because opposing opinions exist in politics, health care, and interpersonal interactions, to name a few, with little effort being spent on finding the middle ground.

Conflict resolution in EM has a critical role with respect to patient care, as well as positive interpersonal and group relationships. Successful communication is integral to promoting positive interactions among individuals in an effort to prevent (or minimize) conflict before it becomes detrimental. Poor communication between individuals may potentiate persistent conflict and misunderstanding. Building alliances with colleagues may reduce the likelihood and amount of conflict. Team building within the ED and hospital that promotes constructive, creative, and cooperative approaches to conflict management is vital to success.
EPs take for granted that difficult interactions occur as part of their daily experience. Some may not find conflict particularly challenging or stressful. Successful EPs must be leaders within the ED despite outside staff not being comfortable with their leadership style. This may be particularly true during stressful situations, a time when EPs gravitate toward the competing style of conflict resolution. Individuals who seldom use the ED (e.g., patients, families, consultants, hospital administrators) may not be comfortable with the environment or its interactions because its structure and culture are “foreign” to them.

Unfortunately, the ED does not always provide the kind of service that health care professionals have come to expect. For example, surgeons in the operating room have instruments handed to them in exactly the way they prefer by designated individuals. This is done in both the patients’ and surgeons’ best interests. In the ED, however, staffing shortages or more pressing cases may result in a consultant being “ignored.” This situation often results in problems for everyone because consultants may take their frustration out on EPs or ED staff. Conflict within the ED is the probable outcome, with the patient and the ED staff suffering. ED staff may feel frustrated that they cannot do better in the eyes of the medical staff, but they are also frustrated by the challenges of staffing, the needs of patients, and the demands of multitasking that prevent them from being more accommodating.

**STRATEGIES FOR SUCCESSFUL CONFLICT RESOLUTION**

With all this conflict occurring in the ED, successful EPs apply strategies to reduce or resolve it in order to preserve the best possible patient and provider satisfaction without compromising patient care. Drs. Marco and Smith describe 10 principles for conflict resolution in EM (Box 4). EPs should make it their “standard of care” to refrain from hostile communication and instead persuade others by using intellect and kindness and focusing on patient advocacy and safety.

These principles seem quite reasonable to adopt into practice. On closer inspection, some are similar to the principles described by Robert Fulghum in his popular book (now in its 15th edition) titled *All I Really Need to Know I Learned in Kindergarten* (Ballantine Books, 2003).

Marco and Smith’s last principle (be pleasant) is good to keep in mind during high-stress situations, when conflict is especially likely to take place. Remember that kindness is contagious. Everyone benefits from a pleasant disposition, regardless of previous negative interactions. Dropping to a lower level of unpleasant or unprofessional interactions during conflict has neither immediate nor long-term benefit and will probably prove detrimental.

O’Mara focused on the interrelationship between communication and conflict resolution. She wrote that “each relationship presents its own potential for ongoing communication dynamics, which may include conflict and misunderstanding,” and added that “appreciating alternative viewpoints and a willingness to adapt are prerequisites for managing interpersonal conflict.” Competent EPs are experts at adapting to many situations, with good communication being a fundamental part of their skill set.

**RELATIONSHIPS IN THE EMERGENCY DEPARTMENT**

Certain unique aspects of the EP-patient interaction may lead to conflict. First, the nature of this interaction is new, intense, unexpected, brief, and unselected. Neither the patient nor the EP chose the other. Furthermore, the balance of power in any doctor-patient relationship is unequal. Each participant has a different perspective on the nature of the emergency condition. Anxiety, pain, cost of care, lost wages, disability, morbidity, and mortality are of great concern to patients. Furthermore, the timing of care—how long is it appropriate to wait for pain relief, test results, consultants, an admission bed, or discharge instructions—creates conflict (and at times open hostility). In these situations, mismatched expectations and perspectives between a patient and an EP result in conflict that can be intensified by stress, pain, and social, cultural, and language differences.

Perhaps the most intense interactions that EPs have occur with nursing, not only because successful interactions are needed at any given moment but also because these interactions occur frequently. Poor interactions between physicians and nurses are often remembered during subsequent interactions. Nurses are likely to interpret words, communication, and body language in the context of previous interactions that were less than ideal. The doctor-nurse relationship has been examined for years because the ability of these two groups to communicate has an impact on patient care. In groundbreaking research examining these relationships, Stein et al. determined that one of the greatest negative influences on patient outcomes occurs when the nursing profession lacks the opportunity to communicate with physicians. EDs that encourage authoritarian behavior and attitudes from their EPs are at

---

**BOX 4 Principles of Conflict Resolution in Emergency Medicine**

1. Establish common goals (e.g., to deliver the best or most appropriate patient care possible in a patient-centered fashion).
2. Communicate effectively.
3. Do not take conflict personally.
4. Avoid accusations and public confrontations.
5. Compromise.
6. Establish specific commitments and expectations (e.g., Who will see the patient? At what time? Who will assume responsibility for care, including admission or discharge orders and/or instructions?).
7. Accept differences of opinion.
8. Ongoing communications (invest in future interactions).
9. Consider the use of a neutral mediator for situations that are not working or become disruptive or emotionally problematic.
10. Be pleasant.

risk for lower morale among nursing staff. This appears to be true in EDs with training programs because the hierarchic nature of training may extend to communication efforts.27 Enhanced relationship building between nurses and EPs includes improved communication styles and techniques aimed at conflict resolution.

Conflict resolution between EPs and medical staff may be difficult to achieve given the episodic nature of interactions, which often occur at inopportune times for both parties. Although the immediate outcome of the interaction may seem appropriate to the EP (serving as patient advocate), the “scars” from this interaction may be deep. Suboptimal interactions may result in several responses, such as avoiding each other, holding ill feelings toward that individual or department, sharing these feelings with others (“professional slander”), or reporting to administrators of the respective departments. In all cases, the earlier that problem interactions are addressed and the more directly, the better that future outcomes are likely to be. Addressing these difficulties with the goal of conflict resolution is best done in a nonthreatening collegial environment. Taking the “personal” out of the problem is always wise, and seeking assistance from a skilled, unbiased “outsider” is a good idea if these problems are not easily handled. Given physicians’ temperaments and busy schedules, outside resources may be difficult to schedule but may be necessary. Resources include chiefs or chairs of respective divisions or departments, ambassadors or communication experts selected by hospital administrators who specialize in interpersonal relationships, ombudspersons, mediators, human resource managers, social workers, licensed therapists, psychologists, and other mental health professionals. These resources may be especially necessary if differences in age, gender, culture, ethnicity, rank, or position exist or if these problems are particularly difficult or have been continuing for some time.30

An additional strategy to foster successful conflict resolution includes engaging with colleagues and staff outside the ED. EPs who participate in medical staff affairs or serve on hospital committees share time with colleagues when stress is not maximal. Positive interactions and sharing common interests during these activities are likely to build alliances, which may reduce the amount and intensity of conflict. Participating in or organizing shared educational activities with colleagues (e.g., journal review, didactic sessions, question-and-answer opportunities) is also important, as long as the goal is education and not criticism. These opportunities allow colleagues with different training to communicate patient care principles, to discuss areas of changing or uncertain practice, and to resolve potential conflict before it occurs. These exchanges allow consultants the opportunity to recognize our knowledge and to see that EPs are interested in gaining skills to provide better patient care and to better accommodate specialty consultants. Furthermore, it is important for EPs to attend social activities within or outside the hospital, where they can get to know medical staff members. Time with non-EM colleagues away from the stressful environment of the ED is a wonderful opportunity for building relationships. This may allow more successful or even faster conflict management in the future.

Much of the best writing on conflict resolution comes from the business literature. The Harvard Negotiation Project found that a working relationship depends on the ability to balance reason and emotion and to understand each other’s interests or position. In the seminal works Getting to Yes: Negotiating Agreement Without Giving In and Getting Past No: Negotiating Your Way from Confrontation to Cooperation, the authors discuss negotiation in terms of it being an everyday experience or a fact of life. These resources describe the method of principled negotiation, which decides issues on their merit rather than through a haggling process focused on what each side says it will and will not do. This method suggests looking for mutual gains whenever possible. When interests conflict, individuals should insist that the result of negotiation be based on some fair standards independent of the will of the other side. This method of principled negotiation is therefore “hard on the merits, soft on the people”21,32 (Box 5). Getting to Yes: Negotiating Agreement Without Giving In recommends that negotiators develop their best alternative to a negotiated agreement, which serves as the basis for exploring and evaluating options.31 This approach involves thinking carefully about what will happen if a negotiated agreement cannot be reached while simultaneously serving as an impetus to engage in a process with agreement as the outcome.

In his book You Can Negotiate Anything, Cohen offers three crucial variables in negotiations: power, time, and information.33 Power is in the hands of the EP in the sense that he or she may use the phrase “I am not comfortable with that (advice),” or “I would like you to come in and see the patient now (let’s discuss this at the bedside).” Power may, however, undermine negotiation and conflict resolution. Those with power have less to gain from negotiation and often walk away from the process (avoidance style of conflict resolution) because withholding participation may maximize their power (or at least not result in its loss). Many authors believe that a collaborative approach to conflict resolution minimizes the role of power in negotiations.

Time is not always on the side of the EP, and it may shift the balance of power to the consultant. Again, the EP must serve in the role of single advocate for the patient; dual advocacy for both the patient and the consultant may result in a conflict of interest and thus jeopardize patient care. Information may be shared among parties. The EP has information about the patient’s condition at the bedside in real time, and the consultant often has a special knowledge base or skill set to offer the patient or the EP. Parties may exchange information that benefits themselves, patients, or both, which must be considered in the conflict resolution “equation.”

Cohen’s mantra for successful bargaining is to “be patient, be personal, [and] be informed.”33 Preparation is important

---

**BOX 5 Strategies for Conflict Resolution from the Business World**

Avoid positional bargaining.
Separate the people from the problem.
Move from positions to interests.
Avoid rushing to premature solutions.
Select and use objective criteria by which to evaluate the fairness of the options generated.
Use negotiation “jujitsu,” wherein one negotiator embraces the other’s positions rather than resisting them.
before negotiations begin, although this is sometimes difficult in EM. Several opportunities exist to increase preparation before consultation (which is a negotiation). Efforts to have the patient’s identifying information available at the start of the conversation, reviewing the laboratory and radiology results before the call if possible, and clearly stating specific goals of the contact (“I need you to come in and evaluate this patient,” or “I need your input on testing, treatment, or follow-up care strategies for this patient”) help reduce conflict before it occurs. Communicating in the consultant’s language and refraining from making suggestions (even obvious ones) unless asked are excellent strategies.

Additional opportunities to achieve conflict resolution include communication that begins with careful, empathetic listening because this allows the other party to feel heard. Avoiding negative comments or ridicule (especially public) and depersonalizing the conflict are healthy approaches to its management. This allows the other party to maintain self-esteem and self-respect. It is important to remain objective and maintain composure while focusing on the issues. Be careful when responding to emotions because it may result in unintended statements with consequences. Silence and time (to compose oneself or gather thoughts) are powerful tools that may deescalate conflict (Box 6).

**BENEFITS OF CONFLICT RESOLUTION**

Dr. Andrew recommended “paraphrasing the communication back to the complainer” and “expressing a willingness to find a common ground.” These recommendations are critical because conflict is often generated (and many times escalated) from fear that a concern was not heard or validated. She described four A’s that assist in conflict resolution to support these ideas:

1. Acknowledge the conflict (“I understand your concern. I can tell you are not pleased with what has taken place.”)
2. Apologize (blamelessly) for the situation (“I’m sorry this situation occurred.”)
3. Actively listen to the concern (“Please go on. I want to hear more about this.”)
4. Act to amend (“I promise I will act to fix this situation and [try to] make certain it doesn’t happen again to someone else.”)

Working together with others can create community, which affords the opportunity to develop creative solutions to resolve conflict. In this manner, conflict can be productive rather than destructive. When possible, an attempt at arriving at solutions acceptable to all involved parties should be made. Addressing differences in values resulting in the conflict (or making resolution difficult), establishing effective styles of communication (including active listening without interruption), and having all parties commit to the mutually satisfying resolution of these concerns are essential factors to success. Given the challenging dynamics of EDs and the instability of groups, prompt conflict resolution is vital to the health of the system. It is especially important to acknowledge shared responsibilities for problems (and solutions) within the ED environment. In this manner, stakeholders have ownership, pride, and incentive to correct the situation. Prevention of potential conflict remains the superior approach to conflict resolution. When this is not possible, early intervention by trained and respected individuals in a safe haven for discussion should be considered.

Skillful negotiating techniques embody an empowering, active, constructive, and positive approach to resolving difficulties and often yield successful outcomes or incremental change over time. Numerous short- and long-term benefits result from successful conflict resolution (Box 7).

**FAILURE OF CONFLICT RESOLUTION**

When it is not possible to resolve conflict in real time, it may be necessary to have an outside mediator work with the parties. Authors on this topic reported in the *Canadian Journal of Emergency Medicine* that “while early intervention through
Conflict has been described as a natural consequence of incompatible behavior and unmet expectations. The preferred strategy for managing conflict is to prevent its occurrence, not easy to do in EM. Effective communication between individuals and within groups in which parties are respected and heard produces an environment of trust. This results in the likelihood that conflict will be resolved more effectively, which benefits everyone. EPs should be aware of their types of behavior and styles of interaction that increase conflict in an environment predisposed to conflict. Furthermore, EPs must strive to understand the principles of conflict and conflict resolution, including effective communication and strong interpersonal and listening skills. Articles discussing professionalism in EM describe the commitment that EPs must make to our profession: suspension of self-interest, honesty, authority, and accountability. These elements are also essential for successful conflict resolution. One article concluded that “Medicine can never succeed as a transaction; it can only succeed as a partnership, a trusting exchange with patients,

BOX 7 Positive Outcomes of Conflict Resolution

- Improved communication with patients and colleagues
- Reduced stress levels and improved staff morale
- Increased workplace productivity (and possibly reimbursement) and reduced expenditures related to conflict
- Promotion of healthy relationships with colleagues and staff
- Improved patient, staff, and physician satisfaction
- Decreased staff turnover (increased staff retention)
- Improved recruitment
- Prevention of future conflict or at least resolution of future conflict more effectively and expeditiously
- Decreased medical errors with improved patient safety
- Improved overall patient care

RED FLAGS ASSOCIATED WITH CONFLICT AND INADEQUATE CONFLICT MANAGEMENT

Because conflict is likely to result in many problems for patients and staff, there are “red flag” areas of conflict and poor conflict management to recognize. In addition to the costs of conflict described earlier, fear of approaching or interacting with EPs or staff members to avoid conflict places patients at risk. For example, an EP may not consult a specialist because of some unresolved conflict in an area outside his or her expertise. Clearly, this behavior jeopardizes patient care and does nothing to improve subsequent interactions.

SUMMARY

Not being aware of personal feelings about conflict. This includes ignoring your “triggers” (words or actions that immediately provoke an emotional response, such as anger or fear). These triggers could be a facial expression, a tone of voice, finger pointing, or a certain phrase. Once you are aware of your triggers, you are more likely to be able to control your emotions and responses.

Not listening to what the other party is saying, including what is not being said. Active listening goes beyond hearing words; it requires concentration and body language that says you are paying attention to the other party. Careful listening means avoiding thinking about what you are going to say next in response to what is being said.

Not acknowledging or understanding differing perspectives, backgrounds, agendas, or goals. This requires being flexible and open-minded.

Not differentiating among positions, their meanings, needs, and facts. It is important to have accurate facts.

Not offering the other party room to admit to errors in judgment. This includes admitting your own errors.

Not recognizing the importance for both sides to feel as though they “won” something (“win-win” collaboration)—in other words, not allowing the other party to experience a winning feeling. Winning at another person’s expense is not winning at all and has no role in conflict resolution. Thus, it is important to include more than one solution to a conflict.

Failing to learn from previous mistakes in conflict resolution. This process is difficult and takes practice.

Not having a plan to follow up and monitor the agreed-on practices. It is important to decide who will be responsible for the specific actions of the plan and how these actions will be monitored (and enforced if necessary).
which is the hallmark of professionalism. The attitudes of and types of behavior by EPs that enhance trust through placing the patient’s needs above other interests serve as the operative definition of professionalism. This philosophy, extended beyond patients to hospital staff members and consultants, suggests the approach that physicians should take to resolve conflicts in EM. Effective communication and interpersonal skills promote a culture of teamwork, which along with professionalism and conflict management techniques, are essential components of successful EM practice (Box 8).

Taoism has as its quintessential ideas guidelines for conflict resolution, which it describes as realizing harmony with one another and achieving consonance with nature. The Art of War, written 2400 years ago by the Chinese military philosopher Sun Tzu, remains one of the most highly influential texts today. Many translations of this work share important philosophical points, such as “winning without fighting” (no conflict) and “knowing your enemies and yourself” (to prevent conflict or, if inevitable, to be more successful in its resolution). In conflict, one must consider the other party an equal, with real issues and needs, and not an adversary to be overcome. Winning at another’s expense does not work if future collaboration is necessary, as is generally the case in EM practice. Successful conflict resolution requires collaboration in which both sides have at least some of their needs met, even if to varying degrees. If one side does not respect the other or if judgment is passed, confrontation will continue and conflict is not likely to be resolved. Truly collaborative solutions, such as those in which both parties feel supported, respected, and satisfied that their needs were met, should be the focus behind the resolution of any conflict.

**ACKNOWLEDGMENT**

Dr. Garmel lectures on the topic of conflict resolution in emergency medicine as part of the National Residency Leadership Curriculum for emergency medicine residents. This curriculum is supported by the American College of Emergency Physicians (ACEP), Society for Academic Emergency Medicine, Council of Emergency Medicine Residency Directors, and Emergency Medicine Residents Association. The Colorado ACEP chapter received a grant that provided funding for the Core Leadership Attribute Seminar Series.

**BOX 8 Comprehensive Approach to Successful Conflict Resolution**

Accept the existence of the conflict.
Focus on the big picture.
Separate the person from the problem.
Clarify and identify the nature of the problem creating conflict.
Deal with one problem at a time, beginning with the easiest.
Engage the respective parties in an environment of impartiality.
Listen with understanding and interest rather than evaluation.
Validate issues and concerns.
Identify areas of agreement; focus on common interests, not on positions.
Attack data, facts, assumptions, and conclusions, but not individuals.
Brainstorm realistic solutions in which both parties benefit.
Use and establish objective criteria when possible.
Do not prolong or delay the process.
Implement the plan.
Evaluate and assess the problem-solving process after implementing the plan (follow up periodically).
The only way to win in the lawsuit game is not to play. If the physician and the suit is dropped or they win in court, they have won. To a large degree, physicians are in the business of comfort and reassurance. Only a doctor knows the difference between feeling bad and being sick. True professionals are persons who do what they do to the best of their ability at any hour of the day or night with people with whom they would least like to do it. Pure science and emergency medicine have very little to do with each other. Truly skilled emergency physicians (EPs) can make patients want what they actually need. Part of the goal of every EP-patient interaction should be an elevation of the patient’s understanding of the disease process and an appreciation for what was required for the diagnosis and treatment.

**SCOPE**

The nature of malpractice—what it is and what it is not—is often difficult for the medical mind to understand. Physicians are Apollonian in upbringing. They believe in science, they believe in what they can see, and they believe in proof. Malpractice is much more a societal concept. It is a battle that takes place in the arena of the court system. The usual concepts that dominate scientific thinking do not hold sway in court. Physicians must come to grips with the idea that ordinary citizens will decide whether they have acted in the best interest of a patient. This never sits well in the hearts and minds of physicians. The general feeling in the medical community is that the medical community should police itself, but this is not how the system is constructed, and physicians must become accustomed to the idea that issues that may seem trivial in the world of science are not so in the world of human interaction.

Medicine is a profession. It is not a pure science. It is practiced on and with ordinary human beings. People respond both positively and negatively to our actions, and this response baffles physicians who have not analyzed the human interaction situation. To a large degree, physicians are in the business of comfort and reassurance. Only a doctor knows the difference between feeling bad and being sick. True professionals are persons who do what they do to the best of their ability at any hour of the day or night with people with whom they would least like to do it. Pure science and emergency medicine have very little to do with each other. Truly skilled emergency physicians (EPs) can make patients want what they actually need. Part of the goal of every EP-patient interaction should be an elevation of the patient’s understanding of the disease process and an appreciation for what was required for the diagnosis and treatment.

**BE SERVICE ORIENTED**

It is a sign of maturity when an EP recognizes that he or she is in a service industry. In a service industry, perception is everything. Perception is the only reality. It makes very little difference whether patients received excellent care if they believed that it was substandard. Bringing the patient and family along in an understanding of the process is essential in proper risk management.

Looking for innate fairness in such a system is a waste of time. No one has ever guaranteed that the court system decides issues fairly. The court system is a mechanism for resolution of social conflict. The courts set public policy and resolve disputes. This does not mean that disputes are always decided fairly or in a scientific context. Courts decide disputes based on human perceptions, and knowing this, the physician can make intelligent decisions about how to practice. Intelligent physicians understand that the patient’s view of the situation needs to be brought in line with the dictates of science. Sometimes this is simple, and sometimes it is not. However, physicians who ignore patients because of indifference or arrogance will soon have a new name: defendant physician. In general, to be named in a medical lawsuit is to lose. Physicians often have the gross misconception that if they are named in a suit and the suit is dropped or they win in court, they have won. The only way to win in the lawsuit game is not to play.

**KEY POINTS**

- Medicine is a business and is therefore covered under the usual concepts of business law.
- Medical-legal considerations are an integral part of every doctor-patient interaction. Complete physicians understand these aspects of care at the same level that they understand the science of such care.
- Human interactive skills reduce lawsuits and improve patient satisfaction.
- The chart is a physician’s lifeboat in a sea of medical adversity.
- The physician is not a bystander in the medical-legal process. The physician needs to be an active participant in the entire endeavor.
- Specific medical-legal situations can be analyzed on a point-by-point basis. Specific actions and documentation programs can go a long way toward reducing legal action.
- Specific medical-legal problems dominate the lawsuit landscape in emergency medicine. Knowing the principal areas of risk and dealing with key points in advance are both good medicine and good risk management.

---

Geetika Gupta and Gregory L. Henry
Everything costs money. Evaluation of complaint letters, initial processing of legal suits, the deposition phase of discovery, and finally, going to court all have their costs. The actual dollar figure to defend lawsuits has risen rapidly since the late 1980s and may constitute up to half the expenses of the insurance company in handling medical-legal actions.

Physicians need to understand the nonfinancial effects of lawsuits on their personality. Excellent information in the literature documents that a physician under suit is much more likely to become depressed. Physicians under the threat of suit also have a decrease in decision-making ability. They have a greater reported incidence of ulcers, divorce, and other social problems. This is understandable when one considers that a physician’s image of self is integrally related to his or her medical degree. The physician has spent a life of study and hard work, from leaving high school to finishing a residency, a period of approximately 12 years, devoted to clinical excellence. When all of this is challenged in the court of law, it hits home to the core of a physician’s soul. The financial cost of malpractice is not the only cost. Any physician who has been sued understands the emotional stress and pain that comes with the process.

Emergency medicine is the ideal setup for poor doctor-patient interactions and malpractice problems. It is when one sees patients at the worst moments of their lives. We often have to make quick decisions on what is an incomplete database. We also have no long-term relationships to provide clues or insight into the nature of the disease. Similarly, no long-term building of emotional bonds exists to prevent the patient from suing should the outcome be negative. In short, emergency medicine is the ideal climate for things that go wrong to be transferred to the legal arena as a means of retribution.

Human psychology leads us to understand that patients will behave as they would like and not as we would like. Residency training programs in the United States do not place a high value on interactive excellence. It is essentially antithetic to the university training program to spend more time on pleasing the patient than on understanding the science. A natural transition occurs when the resident finishes training and moves into a practice setting; a shift in priorities takes place. A young physician does not learn attitudes from books or meaningless statements mouthed at grand rounds. Young EPs learn how to behave and how to practice from watching their fellow, more senior residents and the attending staff who oversee patient care. It is at this level where malpractice will either be won or be lost.

**SMALL THINGS COUNT**

It is often difficult for physicians to understand that small things count. How they are dressed, how they present themselves, how they introduce themselves to their patients, and their use of words may be a bigger factor in whether they are sued than their actual scientific thought processes. The art of medicine is not a “tack on” but an essential fundamental base in creating a productive practice. A doctor who is a great communicator engenders better cooperation and has better results from patients. Such physicians have fewer complaint letters. They receive more help from emergency staff members and consultant physicians and consequently have a less stressful professional life.

Without question, the science of medicine concentrates on two principles: find it and fix it. Diagnosis and disposition are the principal scientific elements of what we do. However, physicians should not underestimate their effect on the thought process of patients in creating an atmosphere of caring. In emergency medicine we are in the “bad outcome business.” It is not whether something will go wrong, but rather when. A physician who has laid proper groundwork with the patient is in a much better position to avoid a medical-legal confrontation.

**BARRIERS TO PROPER CARE**

The EP is often in the position of being emotionally hijacked. Information flows in from patients, their families, nurses, and emergency medical technicians, for example. Frequently, a physician’s perception of a case can be altered by a word or phrase that sets off barriers to intelligent health care. This is the great problem in emergency medicine. Too many times we are prejudiced before we see the patient. When one picks up a chart and the chief complaint says terminal fibromyalgia, recurrent back pain, or recurrent migraine headache, negative connotations and stereotypes often negatively color the doctor-patient interaction before it begins. Certain phrases and situations, again, set off irrational defense mechanisms in the physician that are difficult to overcome. As soon as the patient challenges the physician by asking, “Did you call my doctor yet?,” there is a strong tendency on the part of the physician to take offense.

Whenever a psychiatric diagnosis is written on the chart, beware. Physicians can ascribe virtually any other problem to mental health complaints. This approach is dangerous and can lead one to overlook obvious and treatable diseases. The concept of signal-to-noise ratio dominates information gathering in emergency medicine. We receive so many bits and fragments of information that are truly extraneous to the problem around us that it is often very difficult to focus on the actual patient and the possible disease entity. The physician needs to be aware that these natural human tendencies can manipulate thought processes to the detriment of both the patient and the doctor.

**ESTABLISHING THE RELATIONSHIP**

Good things happen only if they are planned; bad things happen all by themselves. It is important for EPs to have a structured and stereotypic way of greeting patients and gathering information. Some physicians object to this “acting” because they believe that it is somehow beneath their dignity. Nothing could be further from the case. Patients expect and deserve a compassionate physician who will dedicate at least some time to listening to their problem. A careful script is the best way to maintain a sense of decorum and dignity in the interaction. Proper introductions and shaking hands go a long way toward reassuring patients that the physician is there for their benefit. If there is one excellent risk management tool in the ED, it is the chair. EPs should sit down for at least a few moments, if they can, to illustrate to the patient that they are sincerely interested in listening to the patient’s problem. The physician, under our legal system, is the retained agent and
BOX 1 Rules for Physician-Patient Interactions

- It does not matter how long they waited; it was too long. Never argue with patients over the amount of time that they waited.
- Never use excuses, such as you are working short staffed or “I’ve been here all day.” The patient, quite frankly, does not care.
- Always apologize for the wait. As soon as you have apologized for the wait, you have at least acknowledged that the patient’s time is as valuable as yours and you understand that waiting is not a comfortable situation. This is just common courtesy and goes a long way toward making the doctor-patient interaction more desirable.
- Thank people for coming in. Business goes where it is invited and stays where it is appreciated. There is no reason not to thank people for using your institution. It is again common courtesy and is viewed as a sign of acceptance and reassurance by all.
- Trivialization of minor complaints can lead to major problems. Phrases such as “it’s only a virus” are not terribly useful. Patients will listen to your discussion of why antibiotics are not going to be ordered and why further tests are not going to be performed if the reasons are stated in a manner and context that they can understand. Most patients believe that they have a legitimate reason to be in the emergency department. To be scolded because it is the doctor’s perception that theirs is a minor illness never helps the doctor-patient interaction and really does not prevent further emergency department visits. This type of activity is not useful in the long run.

MEDICAL-LEGAL SYSTEM ORGANIZATION AND PROBLEMS

The legal world is divided into two major parts.

Part 1: Criminal acts—These activities are so heinous to the fabric of society that society acts to protect itself.

Part 2: Civil law—This part basically consists of resolution of disputes in which the state acts as the forum for various parties to resolve conflicts.

The history of malpractice is long and varied. As early as the Code of Hammurabi in 1760 BCE, physicians could have their hands amputated if a patient died at surgery. The Code of Justinian in 600 CE also had laws governing physicians and pharmacy. The U.S. justice system is based on English law. Law courts from 1290 CE have records of resolving medical malpractice cases. A lawsuit is again the societal way of resolving a dispute. It takes place in the greater public and civic arena and is not under control of the medical system.

The EP should understand the various types of law. Substantive law states that specific activities are either allowed or not allowed within society. Procedural law dictates when to carry out various activities. Most malpractice falls under the realm of something called common law. Common law is case law. Judges base decisions on what has happened in the past. This is the concept of stare decisis. This Latin phrase, meaning “what has been will be,” states that courts are to decide cases based on the tradition of the law until new law is made. Because we have 50 states, there are 50 different collections of U.S. common law. Although the basic rules are similar, the details vary from state to state. It is essential that EPs know the law in the states in which they are practicing.

All English law is based on the concept of standard of care. The term standard of care is often misunderstood. Standard of care is what an ordinary physician of like or similar training would do under like or similar circumstances. It is not just one action or one mode of care. There are often simultaneously multiple ways of treating a medical condition, and excellent physicians frequently disagree about the best mode of therapy for a particular problem. The standard of care is not the “best” care that may be available. It is what is reasonable. Acceptable care covers a large range of possibilities. In truth, the standard of care is constantly shifting as our knowledge base changes. The standard of care for myocardial infarction in 1960 would certainly be below the standard of care in 2006.

STRUCTURE OF A LAWSUIT

The structural base of a lawsuit has four components. The plaintiff is charged with showing that the physician has violated all these components in some way. First is duty. Duty is what is required by a physician practicing in an emergency department (ED) in the time frame specified by the case. The duty of emergency personnel, for example, to see all patients who come to the ED, has been clear since passage of the Emergency Medical Treatment and Active Labor Act/Consolidated Omnibus Reconciliation Act (EMTALA/COBRA) beginning in 1986. Your duty is to see everyone who comes to the ED and to treat patients up to your level of ability. The next aspect is breach of that duty. The injured party must show that the physician acted in such a way that requirements for performance of that duty were not met.

Harm done is what actually happened. Very often, no matter whether a physician practiced perfect care or did nothing at all, the outcome would be the same. The actual harm done to the patient is an aspect of the case that is often avoided, but it is truly what is compensated in a court of law. The award for malpractice is money, so financial damage must be presented as a part of the process.

Last is the concept of proximate cause. This is the relationship between breach of duty and the harm actually done to the patient. The fact that a patient dies may not be in question. The question is whether the actions or inactions of the physician actually led to the patient’s death. The proximate cause is precisely what expert testimony establishes as part of the civil process.
Physicians often take the position that they are merely injured victims in this system. Nothing could be further from the truth. The physician has the opportunity to participate in and to affect the outcome in every medical-legal situation. The biggest mistakes that doctors make in the legal process are as follows:

- **Ignoring the claim and pretending that it did not happen.** Nothing good comes through registered mail. Physicians must notify their group and hospital whenever a legal summons is issued with regard to the question of malpractice. Physicians can be found guilty and can have monetary damages assessed against them under a default judgment if they do not respond in the proper time frame.

- **Going into a panic and talking to colleagues about the facts of the case.** A physician should not discuss a pending legal action except in the presence of the defense attorney or in the setting of a properly constituted quality assurance meeting. A physician must avoid the temptation to “try the case” with friends.

- **Contacting the patient.** Once a lawsuit has begun, it is absolutely forbidden for the physician to make any calls, write letters, or attempt to contact the patient who has brought the action. Once a specific legal action has been taken, all interaction between parties should be conducted through their attorneys.

- **Failure to preserve the integrity of the chart.** Once a legal action has commenced, the chart should be copied, and the original chart should be sealed and put in a secure place in hospital records. No physician should ever, in any way, alter a medical record after the fact.

- **Failure to assist counsel.** The physician’s input is absolutely required and is mandated in the malpractice policy. Total candor is necessary, and no lawyer likes a surprise. Failure to cooperate with the defense counsel may invalidate a physician’s insurance policy. It must be stressed that you should feel comfortable with the counsel who is assigned to you. If you feel that you are not being represented adequately, ask your insurer for a reassignment or review of the current counsel. Remember that it is your medical license that is on the line.

- **Displaying an arrogant, hostile, or defensive attitude.** Physicians must realize that they are in business. A lawsuit is a part of business. No juror wants to see a physician’s God complex expressed in a deposition or from the stand. A simple, calm, and caring explanation of what actually happened goes best in court. It is important for the physician to not let pride or a sense of injury stand in the way of an intelligent defense.

- **Thinking the trial is a search for truth.** A trial is a dispute resolution process. No truth finding is involved. Lawyers generally do not care about the truth; they care about winning and about the money. Cases are often settled because of the economic implications. Although a case should obtain a verdict for the defense, it may not merit the cost that will be incurred in taking it to trial. If the case does go to trial, everything in the trial matters: the dress and manner of the physician, the personality and politics of the judge, the quality of the lawyers, the degree of sympathy for the plaintiff and family, and the quality of the experts. In this situation, an intelligent physician is an active participant who helps obtain the best experts to help defend him or her in court.

- **Assuming that the legal process will not affect you.** Physicians should take the process seriously, even at a subconscious level. A physician should be prepared to seek emotional help, as well as legal help, when the strain of a lawsuit hits.

- **Knowing when settlement is the right solution.** The physician should not ask a mediocre complaint expert to salvage the case. Not listening to medical and legal experts is a mistake. Certain cases are losers. The person least able to decide whether a case needs to be settled is the physician involved in the case. Other physicians with experience in medical malpractice and who know what wins and loses in court need to be involved in assessing the case. The effect of losing a lawsuit on the group, the hospital, and the emergency contract should not be underestimated.

  Remember to confirm that the settlement release lists your name specifically. If you believe that a case is being pushed toward trial and you are not in agreement, discuss this with your attorney and consider filing a “Bad Faith Claim” against the insurer. This will help secure your personal finances in the event that the case settles higher than your policy limits. The insurer will need to come up with additional funds to cover the verdict. In addition, always entertain discussion of the national databank reporting with your counsel and options regarding the language of the settlement.

- **Casually blaming another provider.** No physician should ever make casual, derogatory comments about anyone else’s care. Physicians are responsible for the care that they have provided, not for the care of other physicians’ patients. Physician infighting raises the cost of cases and does no one, including the patient, any good.

- **Expecting a quick resolution.** EPs, by nature, desire rapid resolution of a problem. Law moves in a time frame of its own. It often takes years to resolve a case. The physician needs to understand that such processes are not what a physician would want.

### CHARTING AND THE MEDICAL RECORD

A medical chart is produced for a reason. Health care workers have less than perfect memories, and as the time wanes from seeing a patient, the exact details also disappear. The principal document in any medical malpractice suit against an EP is the chart generated in the ED at the time of the visit in question. The only things that really go to court with a physician are the patient’s medical record and the physician’s credibility. The chart is the only document that the plaintiff’s attorney has to understand what happened and to be able to decide whether bringing legal action is worthwhile.

Although the chart has multiple functions (e.g., billing, coding, registration), to the EP it is important documentation of the care given. A patient may have received excellent care and have a poor chart, but it is rare that a patient receives poor care when charting is excellent. However, multiple issues with regard to a chart arise in every lawsuit.
LEGIBILITY AND DECIPHERABILITY
Legibility and decipherability are different concepts. It is no longer adequate that a chart be decipherable. Handwritten entries in a chart must be legible to the average person. Actions can now be brought by hospitals against physicians for poor handwriting. Readability also becomes an issue when it comes to discharge instructions. Legibility-related errors in medications or in implementing other therapies are always potentially explosive for a jury.

TIMELINESS OF MAKING A RECORD
All events and entries made on the chart should be timed. When a legal case is reconstructed years later in a courtroom, it is important for the defense to know what happened when. The function of the nursing notes, in particular, is to be a guide to the sojourn of a patient through the ED. When the patient arrives, when triage is performed, when the patient is first seen by the EP, and when various studies are ordered and carried out can become an issue in virtually any case.

CHARTING USELESS INFORMATION
Do what you chart, but chart what you do. Comments on history and physical examination not performed will not go well in court. Vital signs should be determined as needed, but if they are evaluated and found to be abnormal, they should be addressed. Unaddressed vital signs are a significant problem in emergency medicine. Most vital signs do not need rapid reevaluation, but documentation that you have informed the patient that he has, for example, mildly elevated blood pressure that should be followed up by the family physician goes a long way in defending the EP should problems arise in the future.

ALTERING THE MEDICAL RECORD
When medical records need adjustment, such corrections should be made in an obvious and straightforward manner. The EP should never cross out any other health care professional’s note. All additions and corrections to the chart need to be dated and timed. A “doctored record” raises credibility questions. It is important that there be no devious attempt to correct or alter a chart. Nefarious correction of the medical chart is now a federal crime.

ELECTRONIC MEDICAL RECORDS
The electronic medical record (EMR) is here to stay. It has many benefits, including time stamping of orders, records, and charting. It also allows health care workers to access old charts at the push of a button. Along with the good there is the bad. EMRs are notorious for having incorrect information because of pushing forward of out-of-date templates or generic templates. It is critical to review these templates before incorporating the information into the chart. The EMR is also at risk to others using your password-protected access and charting in your name. It is crucial to protect your passwords and sign out once you have left a workstation. The law has yet to define what the standard is now that all the previous records of a patient are readily accessible to the EP, as well as the EP’s responsibility in reviewing them. Finally, remember to read the document or orders before you sign them electronically.

DISCREPANCIES AMONG PROFESSIONALS
Legitimate reasons exist for discrepancies among various professions and what they record in the chart. Histories are taken at different times, patients may refine their histories, and findings on physical examination may change. For this reason, the nursing record needs to be available to the physician. The physician is responsible for the nursing notes generated.

An absolute mistake is to have a negative nursing note written after the time of discharge. What good does it do a patient or a physician for a nurse to write, “Patient still in pain at the time of discharge”? The rules should be obvious. If a negative nursing note is going to be recorded, the physician needs to be informed so that action can be taken. Conversely, the last nursing note does help set the tone of the patient’s condition at the time of discharge. A nursing note stating, “Patient awake, alert, ambulatory, and improved at discharge,” is excellent proof that the patient had received benefit from the ED visit.

COMMENTS ON THE CHART
The chart is a legal document protected by both state and federal law. The chart is not a place where derogatory comments should ever be made. Rudeness and flippancy have no place in medical charting. The chart should reflect the objective observations of concerned health care personnel. Not only are rude generalizations about the patient inappropriate, but they may also prove deadly at the time of trial.

DISCHARGE INSTRUCTIONS
Approximately half the lawsuits in emergency medicine revolve around discharge instructions and the discharge program given to patients. Box 2 presents a few paramount rules for discharge instructions.

SPECIFIC MEDICAL-LEGAL SITUATIONS: PEARLS

The function of this section is to delineate areas where emergency medicine and the law come into direct contact on a regular basis. No practice of medicine brings the forces of the law, society, medical care, general inequities, and resource distribution problems together as does emergency medicine. The ED is under growing stress to solve all social problems. We are being asked to do more and more with less and less until finally we will be expected to do everything with nothing. No other specialty of medicine interacts with general society at the same level as in the ED.

- **Ownership of patients.** Patients own doctors; doctors do not own patients. The legal relationship of parties is that the physician is “the retained agent and servant of the patient.” When a patient is in your department, he or she is your patient from a legal standpoint. The physician cannot abrogate responsibility by saying that the patient belongs to another physician.

- **Combative patients.** The ED has not only the right to restrain but also the duty to restrain when the patient constitutes a danger to self or others by virtue of a physical or mental condition (Box 3). Determination of competency is the key issue. Competent patients may refuse or accept any care that they so chose. Patients who lack such competency will depend on the substitute judgment of the EP. Belligerent patients who are competent require law enforcement to handle the situation.
**BOX 2 Rules for Discharge Instructions**

- All instructions are time specific. It rarely does a patient any good to have a bland statement such as “See your doctor if not better.” That does not tell the patient when to act. Time-specific instructions such as “Return in 6 hours for reexamination of your abdomen or sooner if worse” are clear and to the point. The patient knows what to do and when to do it.
- Instructions must be action specific. It is not adequate to say “Ice a wound.” Do you want it twice per day, three times per day? Should patients use ice directly on the skin or use an ice bag or pack? Patients must know where and when they are going to perform certain acts. The discharge instructions also need to be written in plain language. If a fourth grader could not read the discharge instructions, the instructions are probably inadequate. They need to be brief and to the point. Overly complex and extensive discharge instructions are never read. Discharge instructions need to be separate from information sheets. The instructions are not everything that the patient ever needs to know about a particular disease. They are a list telling the patient what to do, what to watch for, and when to return.
- Abbreviations in discharge instructions can be a serious problem. Most patients are not Latin scholars. They do not know the meaning of the terms PRN and TID. There is always room for confusion when a discharge instruction says “F/U in am.”
- The discharge instructions should be doctor specific. On discharge, a patient should receive a doctor or clinic name and number to follow up with. This avoids the position of abandonment by assuming that the patient has a doctor. “Follow up with your doctor” should be avoided unless the patient and chart explicitly state that the patient acknowledges his own doctor.
- Whenever an untoward delay in patient care takes place, the reason for that delay should be noted. The physician’s memory will not maintain this type of information. If there is an unusually heavy crush of patients to use the computed tomography scanner or some other legitimate reason for delay in care, this should be noted on the chart, as well as any attempts to improve the situation. The physician will have little to no memory of such a situation in 5 years when the lawsuit comes to be tried unless the situation is kept in perspective.

**BOX 3 Rules for Restraining Combative Patients**

- Restraint methods must be appropriate, but both chemical and physical restraints are still commonly used to control patients who constitute a threat. The emergency physician has obligations to other patients in the emergency department and to staff to make sure that a potentially combative or destructive patient does not hurt anyone else.
- When restraining a patient, the need for restraint needs to be documented, the specific mode of restraint needs to be written as an order, and the patient’s basic personal needs require proper nursing care.
- All restrained patients require reevaluation at intervals to determine whether continued restraint is necessary.
- Emergency physicians rarely become involved legally in restraint cases unless they (1) fail to document the reason for restraint and (2) fail to follow their own hospital emergency department’s restraint policy.

**Civil commitment.** In all 50 states, civil commitment is the act of the probate court. The role of the ED is again to secure the patient so that the patient does not cause harm to self or others and to fill out a first certification detailing the behavior and physical findings that justify civil commitment. The observations of the family and police, as well as events seen by the physician, should be documented and used in the decision-making process. Most states require a second certification process to be done in a specified time frame by a mental health professional. In the ED, ruling out organic causes of disease and arranging for the patient to be reevaluated by mental health professionals are the primary goals of evaluation therapy. The authority for civil commitment of a patient is given over to the court system. It is up to the judge to decide on the continued suspension of civil liberties. Proper documentation by the EP that the patient constitutes a danger to self or others by virtue of illness goes a long way toward helping the court system make such decisions.

**Transfers.** EMTALA is the law of the land. A transfer log is a high-profile document that must be maintained by federal law. Informed refusal can allow patients to exempt themselves from EMTALA regulations. Refusal to be transferred should be noted carefully on the patient’s chart by the EP and the nurse involved in the case. The transferring institution has strict legal responsibilities under the law. Stabilization is not an absolute process; it is relative to the needs of the patient. The patient should be stabilized such that the acts of transfer and moving the patient to a higher level of care have a reasonable probability of providing a better outcome for the patient. The appropriateness of transfer is left in the hands of the physician. The transferring institution needs to be able to send laboratory results, radiographs, and any other material obtained from the patient. All such material can be transferred by means other than direct travel, and no unreasonable delays in transfer should take place while awaiting laboratory results. Similarly, records can be transferred by electronic means and should not delay transfer of a critically ill patient. The receiving institution also has obligations under EMTALA. A hospital that usually and customarily receives patients should accept these patients unless their capabilities, at that time, are overwhelmed and they are unable to find room. This fact should be noted on the records when trying to obtain transfer of a patient.

**Reportable illnesses.** The legal system and the ED function together as essentially an officer of the court. Legal reporting duties are mandated by law in every state. Other parts of the hospital (e.g., laboratory) also have obligations to report certain findings to public health authorities.
Reporting statutes vary from state to state. EPs should be aware of and know the reporting requirements in the state which they are practicing. In all 50 states, child abuse, elder abuse, and assaults are reportable illnesses. The EP also maintains a duty to third parties who may not be present in the ED. There is an obligation to protect third parties by reporting to the police. Therefore, when a patient has a gunshot or stab wound, other people may be at risk, and failure to report such injuries could place them in danger. The ED and EP have a clear obligation to see that such reporting takes place.

- **Legal blood alcohol limits.** Legal blood alcohol limits have always been an area of controversy. This is a common problem, but the rules vary from state to state. Determinants for drawing blood and reportable blood alcohol levels are covered in each state under statute. The U.S. Supreme Court has spoken on this issue multiple times. With a court order (i.e., a signed warrant from a judge), the state does have the right to obtain blood alcohol levels. In most states, police officers alone have no authority to force a patient to have a blood alcohol determination made without a warrant. This does, however, vary from state to state because some states have given the police warrant authority to obtain blood. The U.S. Supreme Court ruled against forceful removal of stomach contents with a nasogastric tube. The Court viewed the taking of blood as a usual and customary medical procedure. Passing of a nasogastric tube was considered aggressive and offended the sensibilities of the Court. In no state can the police require the EP to pass nasogastric tubes to obtain samples. However, once a patient has discarded body contents (e.g., vomitus, urine, feces), such material then passes into the public domain, and the police have a right to discarded body contents.

- **Incident reports.** Incident reports are a part of the quality assurance system. In most states, incident reports are protected from both discovery and judicial admissibility. The function of such reporting is to improve care, not to point fingers. The important aspects of incident reports should be clear. The EP should not reference an incident report in the patient’s chart. Medical information about a particular patient belongs in the patient’s records, not in an incident report. Questions concerning the system of care are the proper subject of incident reports. Incident reports should not be filed in a patient’s chart. They are part of a separate system. If they are filed in the chart, they may inadvertently be discoverable should legal action take place.

- **Response to in-house emergencies.** The exact response capability of EPs to sick patients in the rest of the hospital varies from place to place. In large hospitals, this is rarely an issue. In many smaller or rural hospitals, the EP may be the only physician present. General rules should be followed if such care is given. The physician’s contract with the hospital should not have the physician guarantee to be in two places at once. All contracts should be written such that the EP will respond if not required to remain in the ED by the acuity level of other patients. The hospital always has the alternative of placing patients on cots and bringing them to the ED. When the ED is extremely busy, this may be the only reasonable way of handling the situation. When an EP is called to see a sick patient in another part of the hospital, the attending physician should also be called. Someone will be required to rewrite the orders, and someone will be required to speak to the family. The EP should not be viewed as taking over continuing care of the patient. In many states, response to in-house emergencies is considered part of an in-house Good Samaritan statute. This again varies from state to state and should not be assumed.

- **Writing orders for admitted patients.** This area is controversial and difficult. Without question, writing orders can potentially extend the liability of the EP to the in-house setting. Most EPs do not have in-hospital privileges, and therefore writing orders may not be justified. The EP’s medical liability carrier may also have questions regarding orders written on already hospitalized patients. This issue should be explored and settled explicitly with the malpractice carrier. If in-house orders are to be written, specific parameters about when an EP’s responsibility begins and ends should be determined between the ED and the medical staff through the medical executive committee. The best ways to limit exposure on the writing of inpatient orders are as follows:
  - Time-limit all orders.
  - Write only true admitting orders and not continuing care orders.
  - Make it clear when Dr. X, the attending physician, assumes care of the patient.

- **Prescriptions from the ED.** Most medications written by EPs are for up to 10 days of antibiotics and usually for 4 to 5 days of pain medication. This type of prescription constitutes more than 90% of those written. For the EP to renew long-term prescriptions is generally considered inappropriate. Patients who are receiving medications for hypertension or seizures, for example, should be given only enough medication until they can see their own doctor. No long-term doctor-patient relationship is established in the ED, such patients are not monitored for side effects of drugs, and such monitoring is not expected to be done through the ED. Any prescription requiring a Drug Enforcement Agency prescription number should have proper warnings documented on the discharge instructions, along with a copy in the chart. Writing medications for third parties (i.e., enough medication to treat sexual contacts of patients with sexually transmitted diseases) is not a good idea until state laws change to cover EPs for any potential harm that may occur.

- **Doctor-to-doctor conflict resolution.** Conflicts on points of medical care are common in medicine: two doctors, two opinions. When an attending physician and an EP differ on certain issues, the problem must be resolved. Everyone’s story changes in deposition. EPs can be left in a precariously dangerous situation if they have not followed their own instincts. It should be clear on the chart when patient care is managed by another physician. The ED requires a policy on conflict resolution. The ideal policy contains a reference to joint responsibility, obligations of the attending physician to see his or her patients, the ability to refer a case to a neutral third party, and review of all such cases by the executive committee. The EP should beware of powerful, “big admitters” physicians who have unusual control of the executive committee. Such situations can lead to unhappy outcomes for both the patient and the physicians.

- **Patients who leave before examination, who elope, and who leave against medical advice.** Patients who leave before examination are always problematic. Someone must
have seen them to register them in the ED. Capacity is everything. The question of whether the patient had the mental capability to decide to go home is an issue. The last health care professional to see the patient should write a note about why the patient left and attest that the patient had the mental capacity to make such a decision at that time. Eloppement is a similar process in which the patient disappears in the middle of a work-up. In patients in whom we expect eloopment, it is a good idea to take precautions. Placing armbands on these patients so that they will be recognized by security, placing them in visible locations in the ED, and assigning a family member to watch them are all useful techniques. If a patient does elope from the ED, the following should be done:

- Search the ED.
- Have security check the parking and smoking areas.
- Call the patient’s contact phone number.

Informed consent in emergency medicine is rarely an issue or a problem. Informed refusal is, however. Patients who leave against medical advice are using a form of informed refusal. Lawsuits involving patients who leave against medical advice have a very stereotypic formula. It is claimed that the patient was not properly educated about the issues and therefore could not make an appropriate decision. Patients and families can claim that the patient’s mental status was worse than initially presented or that the patient was, in some way, discouraged from seeking medical care. The largest mistake that the EP can make is to believe that signing a piece of paper (i.e., the against-medical-advice form) is the same as following the legal process. It is not. The legal process contains the following:

- Documentation of the capacity of the patient. Does the patient have the mental status and cognitive abilities to act in his or her own self-defense?
- Have we provided the patient a diagnosis in a form that he or she can understand?
- Does the patient understand the consequences of what can happen if he or she does not take the advice of health care workers?
- Have we in some way tried to communicate with family or friends who are with the patient so that they may also be involved in persuading the patient to receive medical care?
- Have all the foregoing been properly documented by both the EP and nursing personnel involved? It is also wise for the EP to have any family or friends present sign the against-medical-advice form or the chart acknowledging that they have heard and witnessed the discussion with the patient and the patient is leaving of his or her own free will. If all the foregoing areas are covered, the EP is virtually suit proof on the issue.

- **Return visits.** In emergency medicine, “bounce-back patients” are always difficult. Frequently, prejudice against such patients exists because they are perceived as not following orders or as doctor shopping. In general, such patients have misunderstood instructions, or the disease entity has changed. Return visits have something that is always potentially dangerous—a diagnosis. The assumption is that the first physician was correct. Unscheduled revisits need to be evaluated, as for any other new patient, to ensure that some obvious change or intellectual blockade in understanding the patient’s health care condition has not occurred.

In general, multiple bounce-backs constitute a serious problem. Some believe that third visits to the ED should result in admission until proved otherwise, although there is clearly no consensus. The possibility of misdiagnosis or mismanagement increases with each revisit.

- **House staff, physician assistants, and medical students in the ED.** The functioning of house staff members can be problematic for many reasons. The actual care given to patients may not be at the same level as care given by attending physicians. The expected standard of care under the law, however, is the same as would be given by a mature physician by virtue of attending-level supervision. All resident work must be supervised if it is to be billed under any federal program. Violations of this mandate are considered criminal violations of the federal law, and the current act has no exemptions. All training programs must follow the guidelines initially promulgated in 1969 and reestablished in 1995. What constitutes supervision has been defined for each specialty and is available and on public record. Ignorance of the law is no excuse. No EP should believe that merely signing the chart actually constitutes supervision of care. Unless the EP has been intimately involved in examination and management of the patient, such care has not happened. The attending physician ultimately bears the responsibility for the acts and omissions of the resident. Off-service residents (i.e., residents called down from another service) are also under the supervision of their attending physicians. When conflict arises regarding what needs to be done with a patient, it should not be resolved among residents, but rather among attending physicians of the various services. The law expects this, and patients deserve it. Physician assistants constitute a different problem. Their payment depends on the level of supervision. Online direct supervision is generally reimbursed at 100% of professional charges. Off-site or added-distance supervision in many states constitutes a lower payment for the services rendered. EPs should be well aware of the laws within their states with regard to the amount of supervision required to bill for such cases.

- **Change of shift.** There are two potentially dangerous times in an ED: July 1, with inexperienced incoming trainees in new roles, and anytime that a shift change occurs. At the change in shift the patient’s care must be transferred from one doctor to another. Continuity of information or insight into the underlying problem is always difficult under these circumstances, and thus a change of shift should be documented on the chart. A note should be made in the chart that the patient’s care was transferred to another physician at a particular time and that discussion was held with this other physician such that he or she is properly engaged in continuing care of the patient. The discharging doctor—the second physician to see the patient—generally assumes the duty to make certain that the patient’s care is complete.

- **Laboratory studies, radiographs, and electrocardiograms.** A general rule is that physicians should not ask a question to which they really do not want to know the answer. If you are going to order a test, you must follow up on the results in some way. A system is required to detect what has been ordered and to account for the results received. Laboratory tests, radiographs, and electrocardiograms must all be interpreted with regard to the specific patient. Follow-up on these issues should be guaranteed. A
system is needed in which each variance in laboratory or radiographic test should be handled within the ED. A general rule is that you should not order tests for which you have no follow-up system. Patients who are admitted are not generally a problem. If tests are going to be ordered that must be followed up by an outside physician, however, this system needs to be guaranteed.

- **Release of information.** The doctor-patient relationship and patient records are protected under federal law. The information within the records is owned by the patient. The actual physical pieces of paper or material on which the record is written is owned by the hospital, and the hospital has a duty to maintain such records. Release of information requires the expressed consent of the patient. A wife, contrary to popular belief, has no implied right to her husband’s medical records. A parent, in the role of legal guardian, has a right to a child’s records but no right when that child is emancipated or has reached the age of adulthood. Casual release of information over the telephone should be discouraged. An individual patient’s right to protection of his or her record is part of the duty of the EP.

- **Duty to a third party.** Duty to a third party is always a difficult question in an ED. Various therapies may render a patient incapacitated in some way and thereby place the patient and others in danger. The very act of issuing a prescription requiring a Drug Enforcement Agency number means that the EP is accepting some responsibility to inform the patient about use of the drug. Patients who drive a car under the influence of heavy medication may injure themselves and others. Without proper warnings, the EP may be involved in litigation. Other devices that make a patient incapable of normal functioning (e.g., the use of crutches, eye patches, and various splints) may also place the patient and others at risk. Discussion of this situation on the chart is useful should the need to provide defense arise.

- **Minors.** State law varies to some extent regarding what constitutes a minor, particularly with regard to emancipation. Emancipated minors are those who live outside the home, provide their own financial support, and make their own life decisions. True emancipation of a minor is the act of a probate court. Nonetheless, minors have rights. In most states, laws exempt certain disease entities from the purview of parents. Also in most states, children who arrive for treatment and are older than 12 years may have questions of child abuse, substance abuse, sexually transmitted disease, and pregnancy treated without parental consent. However, adolescents rarely know these legal rights.

- **Telephone orders and telephone advice.** In general, the ED should not give telephone advice. Telephone advice is not provided in any structured or competent way in most cases, and the EP is frequently unaware that such advice is given. In most cases, patient inquiries and calls for medical advice should be routed away from the EP and nursing staff. Answering machine devices that advise the patient to come to the ED or to call 911 are often the most useful.

**BOX 4 Rules for Orthopedic Conditions**

- There is no such thing as a sprained wrist, just an injury that is not recognized.
- If you think enough of an injury to radiograph it, you should think enough of it to splint it.
- One radiograph does not rule out a fracture. The emergency physician should never guarantee that something is not broken.
- A better approach is to say “Good news! No displaced or obvious fracture” and then explain the limitations of radiography.
- Calcaneal fracture: Examination of the lumbar spine is indicated.
- Spinal fractures in children: The thought process must include the possibility of child abuse.
- Traumatic femoral fracture: Other chest, abdominal, and cervical spine injuries must be considered.
- It is always wise for the emergency physician to let patients know that this is the beginning of a process. Orthopedic management includes recognition, reduction, retention, and rehabilitation. The emergency department is only the first part of what may be a long and complex process.

**SPECIFIC MEDICAL PROBLEMS**

Most suits in emergency medicine are based on the chief medical complaint. The Massachusetts Closed Claims Study indicated that since the early 1980s, the top diagnoses have not really changed. However, the causes of these claims (e.g., failure to diagnose, failure to refer) may not be obvious from just looking at the raw statistics. Much of this section is a word association process. When you think wrist, think navicular bone. This is from a teaching philosophy of automatic response. Associated with each type of chief complaint, very specific yes and no answers should be expressed on the chart to show that the physician has had correct, basic thought processes.

No single chapter of a textbook such as this, indeed no entire textbook, can cover a topic as broad as the intelligent practice of emergency medicine. What is attempted in this section is to alert the EP to issues that have been found to be considerable malpractice problems over the last 25 years. This is not an attempt to teach medicine. That is the function of residencies and continuing medical education. However, the physician should not make obvious errors. This is the low-hanging fruit. The following is a collection of warnings and aphorisms having to do with the practice of emergency medicine that have caused considerable medical-legal constellation.
patient should be guaranteed by the system. The total picture is what is important in emergency medicine. Certain fractures indicate that other actions should be taken. Examples are presented in Box 4.

- **High-risk eyes, ear, nose, and throat or airway.** Airway, in emergency medicine, is everything. Cases involving the airway are major problems because of the serious neurologic injuries that can result. As the disease spectrum in the country has shifted as a result of changes in immunization, the incidence of severe conditions such as epiglottitis has markedly changed. However, because the disease is rare, it does not mean that it does not exist. The decision to control the airway is clinical and is not based on oxygen saturation or blood gas measurements. Proper management of the airway is a core skill required by EPs. Intubation is not necessarily the answer, however. Proper use of a laryngeal mask airway or bag-valve-mask apparatus can frequently control and provide adequate ventilation for patients. The need for minute-to-minute intubation can be modified by other such airway controls. A much rarer, but still recognized complication in emergency medicine is nasal injury. The only condition for which emergency intervention is required is septic hematoma. It should be a quality assurance standard that every patient with a nasal injury have a comment in the chart about the presence or absence of septic hematoma. Radiographs are rarely required for nasal injuries.

When evaluating eye problems, the greatest concern is visual impairment, breach of the globe, or corneal disruption. The infection that occurs may result in blindness. Any impairment in vision or trauma involving the globe should prompt an ophthalmology consultation. Patients with corneal abrasions need to have the potential foreign body removed. Patients need to be educated to not wear contact lenses. They should be discharged with antibiotics and close ophthalmology follow-up to ensure appropriate healing. All patients with only one functioning eye should be referred to ophthalmology for all eye concerns.

- **Wounds.** All wounds seen in the ED are potentially contaminated and have foreign material almost by definition (Box 5). Lawsuits involving wound management by emergency medicine are based on three things: foreign body, foreign body, and foreign body. The cosmetic appearance of a wound is rarely an issue in emergency medicine unless a foreign body has been retained or infection has occurred.

- **Tendon injuries.** Tendons, in the relevant area of a wound, should be tested independently to arrive at the most precise diagnosis possible. Deep wounds should be observed through a range of motion to make certain that the tendon injury is not hidden by soft tissue. There is essentially no reason to explore a tendon sheath in the ED. Repair of tendons is rarely an emergency procedure. These wounds can be properly irrigated and closed loosely, and tendon repair can be performed later, within a reasonable period.

- **Nerve injuries.** Nerve injuries are like tendon injuries. There is essentially no reason for emergency repair of an injured nerve. It is very difficult to assess early in the injury whether a nerve has actually been severed or merely has a functional contusion. The need for proper follow-up is obvious, but immediate intervention is rarely, if ever required.

- **Wound infections.** It is important to let the patient know that the wound has been cleaned. The sink is your ally. Once a wound is disinfected, it is perfectly reasonable to have patients wash out their own wounds. No evidence suggests that sterile saline is any better wound irrigant than tap water.

- **Bite wounds.** Bite wounds are at higher risk for infection, but it depends on the organism involved. Dog bites tend to be less infective than most. Cat bites are highly infective. Human bites are even worse. The physician’s judgment is crucial in all these specific wounds. For a wound that you suspect will become infected, treat it as though you would on the patient’s next visit. Immobilization, intravenous antibiotics, elevation, and short-term interval follow-up are essential.

- **Style points in wound management.** Style points in wound management are essential for patient satisfaction. Pain management is often key. Topical anesthetics placed on the wound are appreciated by patients who have to wait before being evaluated. Long-acting “caine” derivatives are now the anesthetic agents of choice. Sedation may be needed, particularly in children. In view of their safety profile, sedatives should be used on a regular basis.

- **Follow-up and suture removal.** Arranging for follow-up and suture removal is important. Having the wound rechecked and arranging for proper interventions will essentially go a long way in preventing any legal actions concerning wound infections or retained foreign bodies.

- **Poisoning.** Poisoning falls into two general groups. The first group consists of cases of accidental poisoning, mostly involving children. Whenever an EP evaluates a child who has been seen more than once with “accidental poisoning,” the possibility of child abuse or neglect should come to mind. It is not only reasonable but also required that action be taken for the defense of the child. The second group in poisoning is overdose, which involves teens and adults. The science of treating poisoning has changed rapidly. It is generally wise for the physician to consult the poison control center or some other poison authority and to document such contact to make certain that current, acceptable treatments are being used. It is just as important to tell the family that you are seeking such outside expertise in management of the problem.

- **Psychiatry.** In emergency medicine, the major issue with psychiatry is that the physician must be able to delineate organic disease manifested as abnormal behavior (Box 6). All psychiatric patients eventually die of some organic process, and thinking that it is easy to decide what is causing abnormal behavior is often wrong. It is certainly possible to have both a psychiatric diagnosis and an organic problem at the same time. Psychiatric consultation services are often not ideal. It is important to identify who is involved in the

---

**BOX 5 Rules for Wound Care**

- Never guarantee that no foreign bodies are left in a wound.
- Glass is not apparent on radiographs. Liberal use of radiography for shattered glass–type wounds is advisable.
- A laceration chart that does not comment on foreign bodies is probably inadequate.
- Splint wounds of the hand.
evaluation of a patient. Only another physician can truly relieve the EP of liability on the issue. A psychiatric worker from some community program can certainly be helpful and may give an opinion, but if the EP disagrees with that opinion, the EP has an obligation to protect the patient first. The largest single burden on the practice of emergency medicine is patients who are mentally ill or who have altered mental status secondary to drugs or alcohol. There is really no way to dispute that these patients constitute a difficult and common part of emergency practice. When in doubt, the EP should wait until the proper resources are available. The need to restrain and reevaluate patients is a known part of the profession, and it frequently falls to the EP to perform these duties. Clearing patients for psychiatric admission is also wrought with danger. The EP cannot say that a patient is free of organic disease, only that the patient is capable of being evaluated by a psychiatric service. The rule, however, should be that if any doubt exists, the patient should be handled initially by a medical service. Abnormal vital signs should not be ascribed to psychiatric disease. No psychiatric diagnosis causes tachycardia, hyperthermia, or a decreased pulse oximetry measurement. Clues to organic disease include unexplained abnormal vital signs, tremors, and abnormal speech patterns.

• **Chest pain.** This condition is still the largest risk issue in emergency medicine. Between 20% and 25% of malpractice funds expended for emergency medicine are related to the complaint of chest pain. The groups of diseases that constitute most of these cases are acute coronary syndromes, aortic dissection, and pulmonary embolism. The reason that these entities are such large medical-legal problems is that they tend to attack patients in their most financially productive years and can be manifested by diverse and complex symptoms. Coronary artery disease is a common but mysterious disease. Unfortunately, sudden death is often the next manifestation of this disease. No current systems can totally rule out coronary artery disease, but we can at least place the patient in a lower risk category. Pain is highly subjective. Many people describe this pain as a sensation of pressure, or they may have no acute chest pain whatsoever but instead report pain in the neck, jaw, or arms. Patients frequently refer to their pain as heartburn. Physical examination in most patients with chest pain usually reveals nothing (Box 7). Only very unusual cases of nontraumatic chest pain have prominent physical findings. The electrocardiogram is important when it is positive and indefinite when it is negative. Cardiac markers are similar. An initial cardiac enzyme result, if positive, can prompt immediate therapeutic action. A negative enzyme result is just that. It is often too early in the process to know the direction in which the patient is heading.

• **Pulmonary embolism.** Pulmonary embolism is also a difficult diagnosis in many cases. It can commonly be misdiagnosed as pleuritis, pneumonia, or unknown syncope. A psychiatric diagnosis, such as hyperventilation syndrome, is very difficult to defend in court when the patient has died of pulmonary embolism. Work-up of pulmonary embolism has changed markedly in the last few years because of the use of d-dimer testing, Doppler testing of the extremities, and computed tomography (CT) scanning. The age of ventilation-perfusion scanning has essentially come and gone.

• **Aortic dissection.** Aortic dissection is a relatively rare disease. There may be 300 to 500 times more myocardial infarctions than aortic dissections in the United States each year. The symptoms can overlap and may be difficult to diagnose. The EP may consider obtaining a chest radiograph before thrombolytic agents are given. The use of thrombolytic agents for aortic dissection should be discouraged.

• **Abdominal pain.** Lawsuits related to abdominal pain in emergency medicine are highly age and sex dependent because of difficulties in diagnosis. Excellent evidence suggests that up to 50% of the time, a patient with a complaint of abdominal pain leaves the ED without a specific diagnosis proved by testing. Short-term follow-up is the key because examination is merely a snapshot of a moving picture. Gastroenteritis is a frequent diagnosis on lawsuit charts. Entities such as missed appendicitis, arterial disease, and in children, missed meningitis can often be ascribed to gastroenteritis. In the ED it is best to divide abdominal pain into either surgical or medical as general groupings to guide reexamination and therapies. Frequently, we do not have the exact explanation, and this is perfectly acceptable if the patient has been properly instructed and short-term interval follow-up care has been arranged. Abdominal CT scanning is useful, particularly in elderly patients with diffuse disease, but it is not infallible. If a patient’s examination shows peritonitis, remember that CT has a 5% to 8% error rate for appendicitis. Clinical judgment should rule (Box 8).

• **Urologic issues.** In emergency medicine, urologic emergencies are few. With the advent of newer catheter types, the
need for an EP to call a urologic specialist into the ED has become rare. However, some issues have caused considerable medical-legal consternation. Testicular pain needs a diagnosis. A 10-year-old boy with testicular pain has torsion until proved otherwise. Even in a sexually active male patient, the possibility of torsion should not be underestimated. In general, painful testes are best treated after examination and testing with a call or referral to a urologist. A young male patient with testicular pain needs intervention in a timely manner. Overtesting can be a problem. Nuclear scans are not 100% accurate, nor are Doppler ultrasound scans. A young male patient with a painful testicle deserves the insight of a urologist. Sexually transmitted disease can also have long-term sociologic and medical-legal implications. A patient who is being treated for possible sexually transmitted diseases should be asked about partners and should be informed that these partners will also require evaluation and treatment. It is also fair to warn the patient that the public health department will be involved if cultures are positive. The health department has a duty to third parties who have been involved with the patient to seek them out and provide therapy. It may be best for the patient to understand the need to inform contacts and to advise them that they may be at some risk.

• Elevated blood pressure. Elevated blood pressure is found frequently in the ED. Most commonly it is a function of the pain or stress that is related to the chief complaint. It is not the standard to lower all elevated blood pressure. It is recommended that the EP document that no end-organ dysfunction is present and that the patient understands the sequelae of elevated blood pressure. Outpatient follow-up should be recommended to all patients.

• Headache emergencies. Headache is one of the most common chief complaints in emergency medicine (Box 9). The ED must consider the possibility of subarachnoid hemorrhage, meningitis, or carbon monoxide poisoning in every patient with headache. Although subarachnoid hemorrhage is relatively rare in the United States (=50,000 per year), it carries high morbidity and mortality. The most important part of the patient’s history in deciding the possibility of subarachnoid hemorrhage is the rate of onset of the pain. In all long-term studies, this is the key factor in headache pain history. A CT scan is, by itself, not an adequate screen for subarachnoid hemorrhage. A positive CT scan is a positive indicator, but a negative CT scan is indeterminate.

Meningitis is rarely confused with subarachnoid hemorrhage. In a patient in whom meningitis is a serious possibility, the timing of antibiotics is generally the issue at the time of a lawsuit. The EP should feel comfortable about starting therapy early.

• Spinal cord injury. Spinal cord injuries are relatively rare, but they are associated with devastating societal and financial cost. Maintaining a quadriplegic patient costs enormous amounts of money. The ED should properly document immobilization, and there should be no hurry to remove such immobilization. The EP should document an appropriate neurologic examination. Adequate films in patients seriously suspected of suffering cervical spine injury are important. Plain radiographs are becoming less useful, and more and more physicians are advocating an immediate move toward CT of the neck to delineate fractures clearly. The other end of the spectrum is also true. If a patient is awake, has no specific neck complaints, and has no obvious discomfort during examination of the neck, clinically clearing the cervical spine meets the standard of care. The various clinical trials looking at this study clearly point to the uselessness of radiologically pursuing patients whose findings are normal. If there is evidence of bowel, bladder, or motor dysfunction, magnetic resonance imaging should be performed.

• Seizures and syncope. Seizures and syncope can be lethal from multiple perspectives. Injury to the patient is a real potential problem, particularly in patients with seizures. Warnings about driving and the operation of machinery are important for protection of the public in general. Such warnings should be indicated in some way on the patient’s chart.

• Transient ischemic attacks and stroke. Transient ischemic attacks and stroke are becoming larger issues. The American College of Emergency Physicians has gone on record as specifically stating that tissue-type plasminogen activator is not the standard of care for stroke. Lack of rapid evaluation of patients with transient ischemic attacks and initial use of aspirin therapy have been the source of many ED lawsuits. Patients with transient ischemic attacks represent a high-risk group and require timely intervention.

• Trauma. The biggest issue in patients with trauma is too little, too late. Each ED should know what they can and cannot do and should move quickly to ensure that the patient receives the actual help needed. It is useless for a critically

**BOX 8 Rules for Abdominal Pain**

- If the patient still has an appendix, it could be appendicitis. The emergency physician should not avoid this discussion with the patient.
- Repeated evaluations may be the safest and single best test for abdominal pain.
- A few white blood cells in urine do not equal a urinary tract infection; there may be some other cause of the problem.
- In elderly patients with new-onset abdominal or flank pain, think aortic disease as an important diagnosis to rule out.

**BOX 9 Rules for Headache Emergencies**

- If you obtain a computed tomography scan for subarachnoid hemorrhage, perform a spinal tap to confirm its negativity.
- If this is the sudden onset of the worst headache of the patient’s life, it may be his or her last headache and the physician’s worst headache.
- Sudden onset of neck pain can indicate subarachnoid hemorrhage. One third of subarachnoid hemorrhages occur in the posterior fossa.
- If you suspect meningitis, start antibiotics and steroids early.
ill patient to be maintained in an ED and not be moved toward needed surgical rescue. If necessary, the EP in a smaller hospital needs to hold the ambulance or other transfer service to await rapid movement toward the facility of choice. Replacement of fluids and transfusion of blood should not wait for the results of any particular laboratory study. Administration of blood and treatment of shock are critical. Hemoglobin takes time to equilibrate, and patients in shock have no specific abnormal laboratory finding early in the course of the illness. In general, smaller hospitals should understand their capabilities. Excessive radiography is generally useless. Most limb injuries can be splinted, and radiographs can be performed at the receiving institution. The results of laboratory and radiographic studies can be sent after a patient has been transferred. The EP should beware of admitting patients to a hospital that cannot care for these problems. Head-injured patients should not merely be admitted for observation but be sent to a center where intervention can take place if it is actually required.

- **Obstetric and gynecologic issues.** With regard to obstetric and gynecologic issues, it is important for the EP to realize that there may be two patients and not one. The right questions need to be asked. Patients can be inaccurate about the exact dates of their menstrual periods. A urine pregnancy test is an excellent screen, and if it is positive, it is correct at the 99% level. If any question exists, a pregnancy test should be performed. Missed ectopic pregnancies have decreased dramatically in the United States as a medical-legal problem since the widespread use of β-human chorionic gonadotropin testing and ultrasound scanning. Sudden loss of consciousness or shock in a young female patient should raise the possibility of a ruptured ectopic pregnancy until proved otherwise. Eclampsia is the second most common obstetric and gynecologic emergency. Believe the patient’s blood pressure and monitor it carefully. Protein in urine, along with elevated blood pressure, means calling in an obstetrician to become involved in management of the case. In postpartum febrile female patients, ultrasound scans to check for retained products of conception and infection within the uterus are as important as checking the urine. Women who are 5 months into gestation and who have sustained trauma to the abdomen should undergo a period of fetal monitoring. Some legitimate debates exist regarding the length of this monitoring, but most authorities agree that a single reading of the fetal heart rate is not adequate. If a patient is hooked to a fetal monitor over a period of approximately 4 hours, most authorities would consider this a reasonable test to see whether fetal irritability is present.

- **Pediatrics.** The number of pediatric medical-legal cases in emergency medicine has actually decreased as rates of immunization and the various diseases that can be immunized against have increased. The keys to pediatrics are examination and early reexamination. The major issues around febrile children have not changed. The ED needs a protocol for the work-up of children at various ages to rule out infection. No single test can determine whether a child is ill. Important examinations on the chart should refer to the child’s level of consciousness, playfulness, hydration, and activity. A term such as “lethargic child” should prompt reexamination to see whether this is correct. It is true that most adults are more anxious about their children than they are about themselves. The EP frequently needs to convince parents that the child will do well at home. In most well-appearing children, testing is generally useless. Very little evidence indicates that complete blood counts and blood cultures are of use. In particularly young children who are febrile, urinalysis has proved to be a more important screening laboratory study. Feeding of children is important. Offer popsicles or a balanced salt solution of some kind so the parents can actually observe the child eating and keeping food down. The ability to retain fluid is often the reason that children are either admitted or discharged home. Finally, child abuse is a serious social problem seen in EDs. In general, never accuse anyone of abusing his or her child. You merely state that an investigative process is required because of the findings. It is important to emphasize that “they” make us do this type of investigation in these situations. Abuse and neglect are often difficult to separate in the ED, and such distinction needs to be made through social services. When in doubt, however, the child’s safety is paramount, and admitting a child for observation can certainly be a reasonable use of the hospital facility. Certain specific disease entities, such as sudden infant death syndrome, unusual burns, vaginal infections, certain types of fractures, and repeated toxic ingestions, should always be considered suggestive of child abuse until further information is obtained.

**SUGGESTED READINGS**

The word *disparity*, simply defined, implies the lack of parity or the “state of being dissimilar or unequal.” America, historically referred to as “the melting pot,” is a nation whose culture is based on dissimilarity but, ostensibly, on equality. The “melting pot” concept implies that disparities melt away as the nation comes to embody a mixture of qualities from the cultures of all people who live in the United States, thus giving rise to the equality envisioned by the framers of our Constitution. However, no republic in recorded history has ever been able to embody the equality on which it is theoretically based, and the United States is no exception. The words of the Bill of Rights, “all men are created equal,” were rather promptly contradicted by our Constitution’s Three-Fifths Compromise and Enumeration Clause. Parity in representation was not granted to African Americans until the 15th Amendment was passed in 1870, and women were denied suffrage until passage of the 19th Amendment in 1920. Our policies continue to reflect the wish to achieve equality within the realities of our imperfect history.

Disparity in access to care is as old as America itself. Typically, plantation slaves lived in quarters where contaminated drinking water led to frequent outbreaks of cholera, typhoid, and hepatitis and facilitated the transmission of intestinal parasites. Food scraps and human excrement in stagnant water bred the mosquitoes that transmitted malaria and yellow fever. Slave owners usually performed the services of leaching and blistering and administered home medications, with a physician being sent for only as a last resort. Slaves came to distrust the care rendered by owners and overseers and developed their own system of care involving herb root
doctors and midwives.\(^4\) It was not until 1852 that hospital care became available to slaves, when the Jackson Street Hospital was founded in Augusta, Georgia, by a white physician, Dr. Henry Fraser Campbell of the University of Georgia School of Medicine. In 1862, Freedmen’s Hospital in Washington, DC, became the only government-funded hospital for Negroes.\(^7\) Hospitals remained segregated until Executive Order 9981, which mandated the integration of Veterans Administration hospitals, was signed by President Truman in 1948,\(^8\) and the administration of President Johnson forced integration in 1965 by denying federal Medicaid and Medicare dollars to segregated hospitals.\(^10\)

Access to care for members of American Indian tribes was even more restricted. The Bureau of Indian Affairs, established in 1824 by then Secretary of War John C. Calhoun, provided limited health care to the original Americans who had been segregated to reservations. The scope of care was improved when the Indian Health Service was commissioned

in 1955, and access to all hospital care was afforded under the 1965 Medicare and Medicaid legislation.

As recently as 1990, a meta-analysis of 485 articles confirmed that migrant health care was confined almost exclusively to charity migrant clinics, with virtually nothing being known about the health status of the workers. Today, lack of access to care plagues America’s rural areas, where 20% of our citizens are served by only 9% of our physicians. Economic recession and loss of employment have resulted in a decreased number of insured patients to support a rural medical practice.

HISTORY OF DISPARITY IN RESEARCH

With the advent of antibiotics, vaccines, and other drugs to treat human ailments, the findings of basic science became applicable to the medical care of human patients, and with this came the advent of clinical research. The scientific method was applied to medicine as physician-scientists sought to understand the processes of disease and the best ways to treat them. Clinical research proceeded without regulation, and despite the fact that most scientists conducted their work with the good of their patients as the highest goal, several experiments overtly violated human decency and human rights. The most barbaric of all human experimentation was that conducted in the Nazi death camps during World War II (see Table 2). These experiments were, in fact, so unthinkable that physicians and the public saw this as an aberration and did not believe that doctors could ever violate human rights in any other circumstances. However, in 1963, Saul Krugman of the New York University School of Medicine infected severely mentally retarded children at the state-supported Willowbrook School with live hepatitis B virus, both orally and by injection, to test the effect of gamma globulin on progression of the disease (see Table 2). Dr. Krugman had obtained written consent by mail from the mothers of his subjects, but the consent was woefully inadequate in explaining that the children would be deliberately infected with virus. When the Tuskegee experiments were brought to national attention by Jean Heller of the Associated Press in 1972, there was a public outcry against experimentation conducted by the U.S. Public Health Service with tax dollars that violated the rights of U.S. citizens. Both Dr. Krugman and Dr. Taliaferro Clark (the principal investigator on the Tuskegee experiment) justified their actions by stating that these were merely “studies in nature” following the natural course of a human disease.

HISTORY OF DISPARITY IN MEDICAL EDUCATION

Box 1 chronicles the remarkable history of the education of women physicians and physicians of color in a nation that for more than a century made no formal provision for the education of nonwhites and then chose to relegate them to segregated schools with inferior textbooks and equipment. Not only were African Americans pioneers in the advancement of their own education, but their contribution to advancement in many fields of medicine is also significant. Several suggested readings and links are listed at the end of this chapter for readers who wish to learn more.

Despite the progress that has been made, barriers and biases continue to impede the progress of those underrepresented in medicine (URM) and women who choose to enter the field of medicine. An important study in the Journal of the National Medical Association reported that women believed that the specialties they were encouraged to pursue were affected by their gender and that they were often mistaken for nonphysicians. URM students noted that a lack of same-race role models had a negative impact on their medical school experience, and they overwhelmingly reported feeling the need to be “twice as good” to be treated as equal to white students.
DIVERSITY AND CULTURAL COMPETENCY

INTRODUCTION
Racial and ethnic health care disparity has been an issue in the forefront of medicine at the national level since the Institute of Medicine (IOM) report in 2003 highlighted the significant differences in health care experienced by patients and described important ways to address them through diversity and cultural competency.

DEFINITIONS
The definition of some important terms, broadly and more specifically as they relate to EM, will help provide a common understanding and language for the reader. According to the Webster dictionary, culture is defined as “the customary beliefs, social forms, and material traits of a racial, religious, or social group; also: the characteristic features of everyday existence shared by people in a place....” When individuals from the general population come into contact with the health care system, they bring with them their culture and all that it encompasses: their beliefs, values, identity, and links to the community.

According to the IOM report in 2003, the committee defined disparities as “racial or ethnic differences in the quality of healthcare that are not due to access-related factors or clinical needs, preferences, and appropriateness of intervention.”

When people from different cultures and backgrounds come together, diversity is achieved. As defined by the Merriam-Webster dictionary, diversity is the “inclusion of different types of people in a group or organization.” According to the 2010 U.S. census, there are currently more than 300 million Americans: 65.1% white, 15.8% Hispanic, 12.9% black, 4.6% Asian, and 1.2% American Indian or Alaskan Native. Recognizing how the changing patient demographics in the United States should be reflected in the physician workforce, the Association of American Medical Colleges (AAMC) Executive Council in 2003 adopted a definition of URM as “those racial and ethnic populations that are under-represented in the medical profession relative to their numbers in the general population.” Before this, the AAMC used the term “under-represented minority,” which specifically targeted African Americans, Mexican Americans, Native Americans, and mainland Puerto Ricans. A much broader definition of diversity includes racial and ethnic, socioeconomic, sexual orientation, religion, disability, age, language, and geographic diversity.

The Office of Minority Health (OMH) defines cultural and linguistic competence as “a set of congruent behaviors, attitudes and policies that come together in a system, agency or among professionals that enables effective work in cross-cultural situations.”

TOOLS FOR CULTURAL COMPETENCY
The educational concepts for cultural competency are centered around the provider gaining the knowledge, attitude, and skills necessary to elicit patients’ explanatory model of their illness and incorporating it into the medical decision-making process. The skills that lead to this competence are not so different from those that we envision when we think of the ideal humane, compassionate, and caring physician. In the end, this concept helps create a framework that allows the health care provider, with a general approach to any patient from any cultural background, to navigate the cross-cultural experience. In effect, this leads to greater understanding of the patient’s perspective and social context. An important conceptual model recently published by the Agency for Healthcare Research and Quality titled “Can Culture Competency Reduce Racial and Ethnic Health Disparities? A Review and Conceptual Model” describes how integrating nine major cultural competency techniques could potentially improve the ability of physicians and health care systems to deliver appropriate services to diverse populations:

1. Interpreter services
2. Recruitment and retention policies
3. Training
4. Coordination with traditional healers
5. Use of community health workers
6. Culturally competent health promotions
7. Inclusion of family and community members
8. Immersion into another culture
9. Administrative and organizational accommodations

In 2002 the OMH published a practical guide to implement standards for culturally and linguistically appropriate services in health care, and various models and educational programs have been published and are available for health care providers to use. Over the course of time there has been an evolution in the education and assessment of cultural competency in undergraduate and graduate medical education. The Liaison Committee on Medical Education has codified the following criteria: “Students must demonstrate an understanding of the manner in which people of diverse cultures and belief systems perceive health and illness and respond to various symptoms, diseases, and treatments.”

Similarly, the Accreditation Council for Graduate Medical Education (ACGME) has defined its competency standards within two of the six core competencies, patient care and interpersonal communication skills. Numerous other professional organizations have published similar statements promoting cultural competence, including the American Medical Association, the AAMC, the American Association of Medical Students, the American Academy of Nursing, the American Nurses Association, and the American Association of Colleges of Nursing.

Institute of Medicine Committee on Sullivan Commission National Reports
The IOM was charged by Congress with the evaluation of racial and ethnic disparities in health care. The authors published their landmark report “Unequal Treatment: Confronting Racial and Ethnic Disparities in Healthcare” in 2003. They concluded that “Racial and ethnic minorities tend to receive a lower quality of healthcare than non-minorities, even when access-related factors, such as patients’ insurance status and income, were controlled.” It is important to note that the committees focused specifically on disparities in health care and not on health outcomes. The authors outlined two important strategies to help reduce disparities: workforce diversity and cultural competency. The benefits of racial and ethnic diversity among health care professionals include providers who are more likely to serve minority and underserved populations.
communities, greater levels of professional satisfaction, and report of a better educational experience among students. In 2004, the IOM committee and the Sullivan Commission completed their work and issued the following reports, respectively: “In the Nation’s Compelling Interest: Ensuring Diversity in the Healthcare Workforce” and “The Missing Persons: Minorities in the Health Professions.” The Sullivan Alliance, composed of former members of the IOM committee and the Sullivan Commission, aimed to transform the health professions by providing a comprehensive framework that included a total of 62 recommendations from both reports for the health care professions and major organizations.

**Association of American Medical Colleges**

The AAMC has led several efforts targeted at the critical steps referenced by the IOM and Sullivan Alliance. In the 2010 publication “Diversity of the Physician Workforce: Facts and Figures,” the authors reported that between 1978 and 2008, 75% of all medical school graduates practicing medicine were white and that blacks or African Americans, American Indians or Alaska Natives, and Hispanics or Latinos accounted for a combined 12.3% of the U.S. physician workforce. Also worth noting is that over the last 30 years there has been a narrowing of the gender gap, except within the black or African American groups, where in contrast to all other groups, the percentage of women physicians has been greater than that of men. The report identified the U.S. medical schools that historically graduate the greatest number of minority medical students and produce a significant proportion of the minority applicant pool for residency programs. Howard, Meharry, and the University of Illinois have graduated the most black or African American physicians. Oklahoma, North Dakota, and the University of Washington have graduated the greatest number of American Indian and Alaska Native physicians. The Universities of Puerto Rico, Caribe, and Ponce have been the greatest producers of Hispanic or Latino physicians.

Recognizing the challenges and barriers faced by medical schools and academic medical centers in implementing these recommendations, the AAMC has published several road maps to help with these roadblocks. The “Roadmap to Diversity: Key Legal and Educational Policy Foundations for Medical Schools,” the “Roadmap to Diversity: Integrating Holistic Review Practices into Medical School Admission Processes,” and the “What You Don’t Know: The Science of Unconscious Bias and What To Do About It in the Search and Recruitment Process” highlight some of the legal, practical, and subtle barriers, as well as the different levels of commitment required throughout the organization.

Equally important to organizational challenges are the obstacles encountered by individual providers who are susceptible to unconscious bias occurring at the bedside. With this in mind, the AAMC also developed TACCT, a Tool for Assessing Cultural Competence Training, which provides a framework for designing, implementing, and integrating an effective cultural competency educational program.36 The TACCT is a self-administered assessment tool that can be used to examine all components of the curriculum, including problem-based learning, to identify strengths and weaknesses within the program’s educational curriculum. In addition, the ACGME’s Toolbox of Assessment Methods is an excellent resource that includes a description of 13 assessment methods and references to articles in which more complete and in-depth information can be found. The design, implementation, and assessment of effective cultural competency curricula must be flexible, be tailored to the institution, maximize the existing resources, and be linked to a data collection component to measure and monitor for success.

Increasing the diversity of students in U.S. medical schools and ensuring that current physicians are trained to be culturally competent have been cited as key strategies for addressing health care disparities and preparing health care systems for the challenges of the new century. This is especially true for EM because it serves as the hospital’s main entry point, as well as frequently a safety net, for a diverse patient population.

**MOVING TOWARD PARITY IN HEALTH CARE**

Even though access to care has improved remarkably for racial minorities over the past 2 centuries, it is important to realize that they “are disproportionately affected by multiple barriers to care: financial, linguistic, cultural, logistical, organizational, institutional and systemic. Disturbingly, providing disadvantaged populations with adequate access to care may not be sufficient to eliminate racial/ethnic disparities in health.”37 In the Health Disparities and Inequities Report of 2011 by the Centers for Disease Control and Prevention, minority groups were overrepresented in every diagnostic category monitored except suicide and drug-induced death, where whites prevailed.38 Development of cultural competence through the use of tools such as TACCT and the ACGME’s Toolbox of Assessment Methods is an important way for individual physicians to improve outcomes for their patients. However, a systems approach must be used to ameliorate the disparities in disease incidence and outcome that are seen across all levels of health care in the United States. In 2005, the Robert Woods Johnson Foundation launched “Finding Answers: Disparities Research for Change.” This program seeks to identify, evaluate, and disseminate specific interventions that will reduce racial and ethnic disparities in both the care and the outcomes of patients with the specific target diseases of depression, cardiovascular disease, and diabetes. Breast cancer has since been added to this program. Information on specific interventions is available online.39 Another valuable resource for using the systems approach to amelioration of health care disparities is the series titled “Health Affairs: At the Intersection of Health, Health Care and Policy.” This series contains such titles as “Left Out: Immigrants’ Access to Health Care and Insurance” and “Interventions to Reduce Racial and Ethnic Disparities in Health Care.”40

**MOVING TOWARD JUSTICE IN RESEARCH**

History documents that although man’s humanity toward his fellows has always been inspirational, even in the direst of circumstances, man’s inhumanity toward his fellows has been appalling, even in the best of circumstances. Following the Allied victory in World War II, the Nuremberg War Crimes Trials included proceedings to develop a code of ethics
addressing the issue of consent in human experimentation. The Nuremberg Code was established in 1948 and stated that “The voluntary consent of the human subject is absolutely essential.”43 Concern for human rights has remained in the forefront of world consciousness since that time. In 1964, the World Medical Association chose to address this issue at a meeting of the organization in Finland. The Declaration of Helsinki was established to guide medical doctors in biomedical research involving human subjects. It governs international research ethics. It was revised in 1975, 1983, 1989, 1996, 2000, 2002, 2004, and 2008 and is the basis for the good clinical practices used today.

Issues addressed in the Declaration of Helsinki include the following:

• Research on humans should be based on results from laboratory and animal experimentation.
• Research protocols should be reviewed by an independent committee before initiation.
• Informed consent from research participants is necessary.
• Research should be conducted by medically or scientifically qualified individuals.
• Risks should not exceed benefits.42

When particularly shocking acts of injustice and abuse occurred in Tuskegee and at Willowbrook despite the codes of ethics established at Nuremberg and Helsinki, the U.S. government charged the Department of Health, Education and Welfare with developing standards for protecting subjects of human research. Three fundamental ethical principles were put forth in their report:

1. Respect for persons: Protecting the autonomy of all people, treating them with courtesy and respect, and providing for informed consent. Researchers must be truthful and conduct no deception
2. Beneficence: The philosophy of “Do no harm” while maximizing benefits for the research project and minimizing risks to research subjects
3. Justice: Ensuring that reasonable, nonexploitive, and well-considered procedures are administered fairly—fair distribution of costs and benefits to potential research participants—and equally43

In the United States, the Belmont Report remains the standard by which institutional review boards (IRBs) ensure that subjects of human research are treated with respect for persons, beneficence, and justice. The report states that “Injustice arises from social, racial, sexual, and cultural biases institutionalized in society. Thus, even if individual researchers are treating their research subjects fairly, and even if IRBs are taking care to assure that subjects are selected fairly within a particular institution, unjust patterns may nevertheless appear in the overall distribution of the burdens and benefits of research.”44 Equal opportunity to benefit from research has come under scrutiny recently. Theoretically, diseases that predominantly affect racial and ethnic minorities and low socioeconomic groups should have the same opportunity to be studied as diseases predominantly affecting males and whites. Over the past decade, however, there has been concern regarding the lack of inclusion of women as subjects of research45 and inadequate inclusion of blacks and Hispanics in human immunodeficiency virus research.46 Because trauma is predominantly a disease of racial and ethnic minorities, the poor, and the undereducated and because these populations are regarded as vulnerable by IRBs, there are significant barriers to conducting trauma research. Several EM researchers have questioned whether there exist vulnerable populations in conditions in which acute loss of decisional capacity makes all patients equally vulnerable.47 Others question whether the standard informed consent process, refused more often by black than by white patients, may not introduce bias into research studies by underrepresenting disease among minority patients.48 Because EM research is predominantly conducted by EP-scientists, our specialty must continue to take the lead in ensuring that all patients have equal access to the benefits of research while they are equally respected and protected from potential abuse.

Increasing the diversity of the medical student population and ensuring that physicians are trained to be culturally competent have been cited as key strategies in addressing health care disparities. The concept of concordance,49 or phenomena by which patients prefer physicians who mirror their own cultural and ethnic backgrounds, values, and communication styles and express more satisfaction when cared for by doctors of their own race, emerges as another convincing factor in favor of increasing diversity of the physician workforce. Yet despite increasing evidence of the benefits of physician diversity, we have been slow to change. In 2004, 6.6% of U.S. medical students were Latino and 7.3% were African American. Today, although 16% of the U.S. population is Latino and 13% is African American, only 7.9% of medical students are Latino and 7.1% are African American.50 In 1963, Dr. W. Montegue Cobb, in discussing the reasons for the dearth of Negro physicians in the country, cited the inferior quality of education offered to many African Americans, inadequate financial resources, and “failure to become oriented toward medicine and its exacting requirements early enough.”51 It is unfortunate that almost 50 years later, these continue to be the reasons for the dearth of URM physicians in this country. The National Medical Association and the National Hispanic Medical Association continue to take the lead in nurturing URM high school and college students to consider medicine as a career and to nurture residents toward success. The Diversity Interest Group of the Society for Academic Emergency Medicine (SAEM)52 provides virtual and real-time advise and support to minority students interested in EM, especially those at schools of medicine without an academic department of EM or an EM residency program. Our organization is available to students of color at their Emergency Medicine Interest Group meetings, and we attend the student sections of annual meetings of the National Medical Association and National Hispanic Medical Association. Mentoring in Medicine (MIM),53 an organization started by EPs at Montefiore Medical Center in the Bronx, New York, provides a pipeline program beginning at the elementary school level to encourage URM children in their desire to become health care professionals and to facilitate this desire through mentoring,
Despite this national mandate, the face of medicine, including EM, has been slow to change and reflect the evolving patient demographics. Between 1978 and 2008, the AAMC reported a workforce totaling 471,409 physicians. Of all medical school graduates practicing medicine, 75% were white, whereas African Americans, American Indians and Alaska Natives, and Hispanics or Latinos accounted for a combined 12.3% of the U.S. physician workforce. This is in stark contrast to the 30% URM composition of the general population in the United States. Similarly, the specialty of EM in 2008 had a total of 25,516 practicing physicians with a breakdown by race and ethnicity of 78% white (20,016) and 12% minority groups (1474 African American, 1365 Hispanic or Latino, and 156 American Indian). In comparison to the survey conducted in 1997 by the SAEM Task Force on Women and Minorities, there has been some progress. With a 76% response rate by EM full-time faculty at 105 EM residency programs, minority faculty represented 9% of those surveyed (4% African American, 2% Puerto Rican, 2% Native American, and 1% Mexican American). Additional problems are presented by the very nature of EM practice. We care for the most disadvantaged and vulnerable racial and ethnic minority populations. The fast-paced and unpredictable clinical setting of the ED has numerous challenges that may lead to disparities in care, including time constraints, limited information, and inadequate resources. The ED health care team must establish rapport quickly and gain a sense of trust from the patient and family. Patients who are acutely ill, sometimes with a language barrier, represent some of the most challenging patients for emergency providers and are at the highest risk for suffering from unconscious bias, disparities in care, and worse outcomes.

According to the IOM and Sullivan Alliance reports, the specialty of EM should adopt the two broad strategies recommended to help reduce racial and ethnic health care disparities by proactively recruiting a diverse workforce and training students, residents, fellows, and faculty in cultural competency.

**LEADERSHIP STRATEGIES**

Our specialty has been a leader in the clinical and educational realms when it comes to raising awareness, promoting discussions, and developing strategies around diversity and cultural competency. This is evident by the professional organizations, consensus conferences, and work groups that have convened leaders from the broad membership of EM to develop and publish policy statements, recommendations, considerations, and tools for the specialty to implement in their programs and departments.

**ORGANIZATIONAL LEADERSHIP**

The SAEM’s Diversity Statement (2000) states “Attaining diversity in emergency medicine residencies and faculties that reflect our multicultural society is a desirable and achievable goal.

- “SAEM encourages all academic medical centers to recruit, retain, and advance a faculty reflective of the community served.
- “SAEM encourages its members to respect, support, and embrace the existing cultural differences of its membership.
- “SAEM encourages the development of didactic, educational, research, and other programs to assist academic emergency medicine departments to improve the diversity of their faculties and residencies.”

The American College of Emergency Physicians’ Policy Statement on Workforce Diversity in Health Care Settings (2001) states that “Hospitals and emergency physicians should work together to promote staffing of hospitals and their emergency departments with qualified individuals who reflect the ethnic and racial diversity in our nation, as well as, attaining diversity with well-qualified physicians in emergency medicine residencies and faculties that reflects our multicultural society is a desirable goal.”

**SOCIETY FOR ACADEMIC EMERGENCY MEDICINE DISPARITIES CONSSENSUS CONFERENCE (2003)**

In 2003, the Society for Academic Emergency Medicine held a national consensus conference titled “Disparities in Emergency Health Care” that focused on racial and ethnic disparities in emergency health care and how to reduce them by implementing two key strategies. The conference brought together leaders from across the country, developed key working groups to discuss disparities in emergency health care within the clinical and educational realms, and encouraged further research.

Their findings and recommendations were published in a special issue of *Academic Emergency Medicine*. The following is a summary of their goals and strategies for implementation:

In the clinical practice of EM:

1. Increased awareness and use of continuous quality improvement methods to document individual and institutional disparities in performance
2. Increased use of evidence-based clinical guidelines and pathways
3. Zero tolerance for stereotypic remarks in the workplace
4. Cultural competency training for emergency providers
5. Enhanced linguistic services
6. Increased workforce diversity
7. Increased epidemiologic, clinical, and services research

In education and training of EM:
HEALTH CARE DISPARITIES AND DIVERSITY IN EMERGENCY MEDICINE

1. Establishment of diversity training as part of the ACGME program requirements for EM
2. Organizational leadership for changing the values and priorities of the specialty
3. Faculty education and training on cultural diversity
4. Graduate medical education of EM and off-service residents with an organized curriculum in diversity, including standardized patient encounters, case discussions, and focus groups of residents and medical students that allow in-depth discussion and learning
5. Undergraduate medical education of medical student training in the clinical setting by culturally competent residents and faculty members

THE PROMOTING DIVERSITY IN EMERGENCY MEDICINE RESIDENCY DIRECTORS ACADEMIC ASSEMBLY DIVERSITY WORKGROUP (2009)

In 2009, the Council of Emergency Medicine Residency Directors (CORD) Academic Assembly convened a national Diversity Workgroup aimed at promoting diversity in EM and published a set of primary recommendations, secondary considerations, and tools to help EM residency training programs and departments.

Their findings and recommendations were published in the journal Academic Emergency Medicine. The following is a summary of their goals and strategies for implementation:

The primary recommendations are:

1. A proactive and welcoming approach to recruiting students from diverse racial and ethnic backgrounds
2. Knowing the institution’s local and community demographics and addressing these needs by also providing a mix of providers who reflect the diversity of the patient population
3. Validating the importance of applicants meeting residents and faculty from diverse backgrounds when they come to interview while paying attention to “racial fatigue”
4. Broadening the selection criteria to include not only U.S. Medical Licensing Examination scores, the Medical School Performance Evaluation, and letters of recommendation but also meaningful intangibles such as leadership, community service, and other relevant life experiences

The secondary considerations are:

1. Developing curricula to address topics on diversity, cultural competence, and implicit bias
2. Being proactive and committing early to the success of diverse residents in the program
3. Becoming familiar with resources available to encourage medical students to pursue a career in EM, which may include engagement with organizations that focus on minority health concerns such as the National Medical Association, Student National Medical Association, and National Hispanic Medical Association
4. Celebrating visible success of the program’s attention to diversity, such as increased numbers, educational initiatives, and promotions

The tools described by the workgroup to help programs with the recommendations and considerations are:

1. Roundtable discussions and conferences on various aspects of diversity during resident orientation, during retreats, and throughout the academic year
2. Organizing interview dinners and social events for students and residents from diverse backgrounds
3. Use of exercises, role-playing, and the Implicit Association Test, a collection of short online tests reflecting one’s unconscious racial, ethnic, and social biases, to help with diversity initiatives (http://www.implicit.harvard.edu)
4. Use of the Cultural Competency Curriculum Task Force Monograph for articles and case studies that address cultural competence (http://www.meded.virginia.edu/courses/culture/)
5. Use of any institutional resources such as an Office of Diversity or Multicultural Affairs
6. Inclusion of diversity in the department’s mission statement and in all recruitment material and departmental and institutional websites and highlighting it as a core value of the program
7. The SAEM’s Diversity Interest Group as a resource
8. Pamphlets and websites that highlight diversity
9. Inviting nursing, ancillary personnel, and colleagues from diverse backgrounds in other departments who are willing to discuss issues of cultural importance with applicants

FUTURE DIRECTIONS

Elimination of disparities and development of a diverse, culturally competent workforce will require the collective effort of individual providers, EM residency programs, faculty practices, hospital administration, and medical school leadership in embracing the goals of delivering equal care to all. In closing the gap in health care disparities, EM leaders and educators will play a critical role by recognizing disparity as an important issue in medicine and by developing methods of addressing the knowledge and attitudinal barriers that propagate the problem. As the population continues to become more diverse, we will need to quickly expand the professional pipeline from high school to faculty leadership positions to meet the public’s need. The development and implementation of cultural training that is compliant with the ACGME core competencies should provide our residency graduates with the skills that they need to be effective, culturally competent practitioners. Increasing workforce diversity and ensuring cultural competency are the most important strategies for eliminating racial and ethnic disparities in health care.

SUGGESTED READINGS

The following readings are excellent papers that reference the IOM recommendations or the 2003 SAEM national consensus conference “Disparities in Emergency Health Care.” Recommendations and practical information on applying the recommendations are provided. The Hobgood and Sawning article reviews several models for teaching cultural competency. The
Cone and Richardson article provides a succinct but thorough synopsis (their Table 1) of the findings contained in the IOM “Unequal Treatment” report.

The following is a very interesting article on the contributions of African Americans to both advancement of medical science and elimination of health care disparities. This is a magazine article and not a journal article, so it does not contain references. As early as 1963, Dr. Cobb realized that the reasons why so few Negroes were entering medical school was that they were not qualified because of inferior educational opportunities, they did not have the financial ability to attend, and they simply did not think that becoming a physician was an option for them. He stressed the need for programs that reach out to these young people, encourage them to think about careers in medicine, and assist them in meeting the requirements of medical school. We are still advocating these interventions today.

A comprehensive compendium of the history of African Americans in medicine can be found at www.mclibrary.duke.edu/hom/exhibits/blkhist. Extensive information is available about African American physicians, medical schools and education, black hospitals, folk medicine, and achievements of black men and women of science.

For an inspirational look at the many women who were and are pioneers in the various fields of medicine, look at the National Institutes of Health website www.nlm.nih.gov/changingthefaceofmedicine/physicians/biography. This is the most comprehensive site for information about female Native American physicians.

The following interesting study demonstrates that underrepresented minority physicians gain better pain control with less analgesia for patients of all races than do white physicians:

Another informative study looks at the possibility that systemic bias may be resulting in underreporting of disease in underrepresented minority populations:

• Go to http://www.saem.org/SAEMDNN/Portals/0/Newsletters/2010/JulyAugustNewsletter2010.pdf to see “President’s Message” in the Society for Academic Emergency Medicine (SAEM) Newsletter of July/August 2010. In his first column as SAEM President, Jeffrey Kline, MD, takes a realistic look at Arizona statute sb1070 and the possible impact on access to care for Arizona’s Mexican immigrants.

The following provocative article looks at vulnerability and justice in resuscitation research:
